Ions

Ions are charged species.
This is due to a gain or loss of electrons (almost never protons!)

Gain of electrons → negatively charged ion ≡ **anion**
Loss of electrons → positively charged ion ≡ **cation**

There are two types of ions: simple and complex

Simple ions

Simple ions (monoatomic ions) are species with one nucleus that has gained or lost electrons

F^- (anion) = $^{9}F^{9+}$ + 10 e^-
Ca^{2+} (cation) = $^{20}Ca^{20+}$ + 18 e^-

Complex ions

Complex ions are molecules, where the atoms are connected by covalent bonds, that have lost or gained electrons.
Those are also called polyatomic ions

Examples: NH_4^+ ammonium ion or H_3O^+ hydronium ion

Note that polyatomic ions themselves do not break apart

More examples can be found in **Table 2.2 of M & H p. 41**

Compounds can also be formed the interaction of anions and cations (species of opposite charge)

These are called ionic compounds even though they are electrically neutral (# of positive charges = # negative charges)

Such compounds are held together by an electrostatic attraction known as an ionic bond

Crystalline table salt (NaCl) is Na^+ and Cl^- bonded together.
When dissolved, NaCl dissociates to form a solution of Na^+ and Cl^-

Names of Compounds

A compound can be identified using its formula (NaCl) or its name (sodium chloride).
The following are conventions used in naming compounds:

1. Ions

Simple (monoatomic) cations of metals take the name of the metal

Na^+ = sodium K^+ = potassium

However, some metals, specially transition metals in the periodic table, exist in more than one cationic form.
To distinguish these, we note the charge as a Roman numeral

Fe^{2+} = Fe(II) Fe^{3+} = Fe(III)

Simple (monoatomic) anions are named by adding the suffix **ide** to the base name of the non-metal

Cl^- = chloride O^{2-} = oxide H^- = hydride

Polyatomic ions are given special names (see **M&H Table 2.2**).
However, those containing oxygen (oxoanions) can be names using the base name and the following rules:

When the non-metal forms only two oxoanions, the suffix **ate** is used for the one with the more oxygens.
The suffix **ite** is used for the one with the least oxygens

SO_4^{2-} = sulfate SO_3^{2-} = sufite

When a non-metal forms more than two oxoanions, we use the prefixes, **per** and **hypo** for the **most** and least oxygens, respectively

ClO_4^- = perchlorate

ClO_3^- = chlorate

ClO_2^- = chlorite

ClO^- = hypochlorite

2. Ionic Compounds

Recall that ionic compounds consist of a cation and an anion.
It follows that they are named using the names of the cation and the anion (also the order which they are written)

NaI = sodium iodide

NH_4Cl = ammonium chloride

$FeCl_2$ = iron(II) chloride

FeCl = iron(I) chloride

Note: the Roman numerals are used as appropriate

3. Binary Molecular Compounds

The combination of two non-metals usually forms a binary compound.
They usually contain two-worded names

The first word corresponds to the first element in the formula, with a Greek prefix to show the number of atoms of that element

2 = di 3 = tri 4 = tetra 5= penta 6 = hexa
7 = hepta 8 = octa 9 = nona 10 = deca

The second word uses the stem name of the element, the Greek prefix, and the suffix **ide**

Examples: N_2O_5 = dinitrogen pentaoxide
NO_2 = nitrogen dioxide
N_2O = dinitrogen oxide

Many binary compounds have accepted common names:

H_2O = water NH_3 = ammonia
H_2O_2 = hydrogen peroxide C_2H_2 = acetylene

4. Acids

Some binary compounds ionize in water to form H^+ ions, and are called **acids**.
For example, when hydrogen chloride is dissolved in water it forms H^+ and Cl^- ions.

$$HCl(g) \xrightarrow{H_2O} H^+(aq) + Cl^-(aq)$$

The water solution of HCl is called hydrochloric acid

Acids that also contain oxygen are oxoacids.
Two common ones are nitric acid (HNO_3) and sulfuric acid (H_2SO_4)

The names of oxoacids originate from the names of the corresponding oxoanions.
The suffix ***ate*** is replaced with **ic**, and ***ite*** is replaced with **ous**

Examples:

ClO_4^- = perchlorate ion — $HClO_4$ = perchloric acid

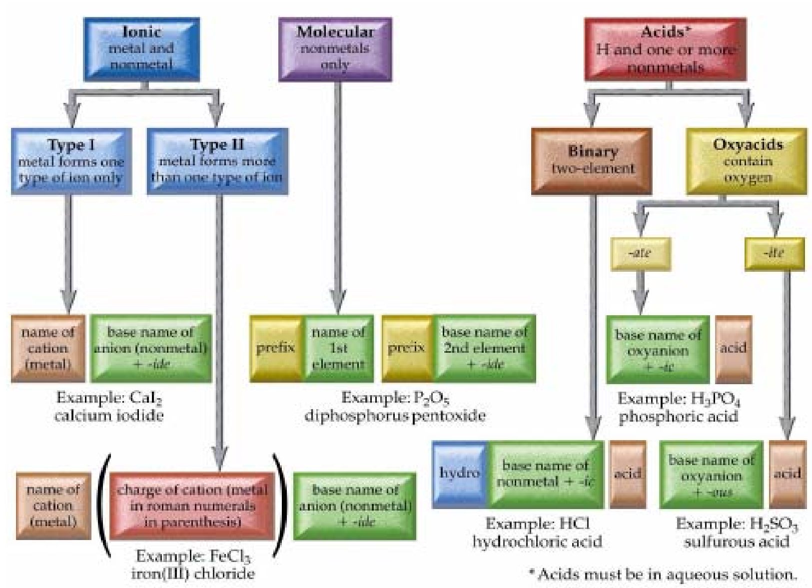
ClO_3^- = chlorate ion — $HClO_3$ = chloric acid

ClO_2^- = chlorite ion — $HClO_2$ = chlorous acid

ClO^- = hypochlorite — $HClO$ = hypochlorous acid

Note: polyanions do not “break apart”.
In the example below, sulfate stays as sulfate

$$H_2SO_4 \xrightarrow{H_2O} 2H^+(aq) + SO_4^{2-}(aq)$$



The mole *(M&H Ch. 3)* (relevant problems found in tutorial manual section Stoichiometry Part 1, p. 17…)

The unit for chemical mass is the **mole**

≡ "the mass (in g) of an element or compound equal to its average atomic mass (in amu)"

▪usually denoted by symbol "n"

For example 1 atom of C weighs 12.01 amu while 1 mole of C weighs 12.01 g

That methane, CH_4: one molecule weighs [12.01 + 4(1.01)] = 16.05 amu while one mole weighs 16.05 g

> One mole of a substance always contains the same number of particles
> = 6.022×10^{23}
> ≡ Avogadro's number, N_{AV}

Compare 1 dozen = 12 units; 1 mole = 6.022×10^{23} units

For example: 1 mole of O_2 = 6.022×10^{23} O_2 molecules = 32.0 g

1 mole CH_3CH_2OH contains 6.022×10^{23} ethanol molecules = 46.0 g and contains $9xN_{AV}$ = 5.42×10^{24}atoms total
of which $6 \times N_{AV}$ = 3.61×10^{24} are hydrogen atoms, $2xN_{AV}$ = 1.20×10^{24} are C atoms, 6.022×10^{23} are O atoms

The **molar mass** of a molecule is the **sum** of the individual atomic masses.

For example the molar mass of CH_3CH_2OH = 12 + 3 + 12 + 2 + 16 + 1 = 46.0 g mol^{-1}

Molar mass also termed the **molecular weight** or for ionic compounds such as NaCl, the **formula weight**

Worked Example:
If coal is 3.00 % by mass sulphur, S, how many moles of S are contained in 1 tonne (1000 kg) of coal?

Mass of S in 1 tonne of coal = (3.00/100.0) x 1000 kg = 30.0 kg

30 kg = 30.0 x 10^3 g. $\therefore$ The number of moles, n = (30.0 x 10^3 g)/32 g mol^{-1}

n = 940 mol $tonne^{-1}$

Molecular Formulas

Given a molecular formula, one can calculate the % composition of the elements present:

Worked Example:
for ethanol, CH_3CH_2OH = C_2H_6O the molar mass = 46 g mol^{-1}

Mass of C in compound =12 x 2 =24

$\therefore$ %C = (24.0/46.0) x 100% = 52.2%

Similarly, %H = ([6x 1.01]/46.0) x 100% = 13.2%
and
%O = (16.0/46.0) x 100% = 34.8%
