Discover Abitibi
A project of innovation, cooperation and revitalization

Découvrons l' Abitibi
Un projet d' innovation, de coopération et de renouvellement

Discover Abitibi Initiative
The Discover Abitibi Initiative is a regional, cluster economic development project based on geoscientific investigations of the western Abitibi greenstone belt. The initiative, centred on the Kirkland Lake and Timmins mining camps, will complete 19 projects developed and directed by the local stakeholders. FedNor, Northern Ontario Heritage Fund Corporation, municipalities and private sector investors have provided the funding for the initiative.

Initiative Découvrons l'Abitibi
L'initiative Découvrons l'Abitibi est un project de développment économique régional dans une grappe d'industries, projet fondé sur des études géoscientifiques de la ceinture de roches vertes de l'Abitibi occidental. Cette initiative, centrée sur les zones minières de Kirkland Lake et de Timmins, mènera à bien 19 projets élaborés et dirigés par des intervenants locaux. FedNor, la Société de gestion du Fonds du patrimoine du Nord de l'Ontario, municipalités et des investisseurs du secteur privé ont fourni les fonds de cette initiative.

Open File Reports of the Ontario Geological Survey are available for viewing at the Mines Library in Sudbury, at the Mines and Minerals Information Centre in Toronto, and at the regional Mines and Minerals office whose district includes the area covered by the report (see below).

Copies can be purchased at Publication Sales and the office whose district includes the area covered by the report. Although a particular report may not be in stock at locations other than the Publication Sales office in Sudbury, they can generally be obtained within 3 working days. All telephone, fax, mail and e-mail orders should be directed to the Publication Sales office in Sudbury. Use of VISA or MasterCard ensures the fastest possible service. Cheques or money orders should be made payable to the *Minister of Finance.*

Abstract

The two-year research project funded under the Discover Abitibi Initiative involved 1:10 000 geologic mapping of regional gold-hosting structures and detailed studies of gold occurrences in Gauthier and Teck townships (Kirkland Lake–Larder Lake area, Abitibi greenstone belt, Ontario). The project focused on gold occurrences along the regional, roughly east-trending Larder Lake–Cadillac deformation zone, the northeast-trending Upper Canada deformation zone, and the brittle to brittle-ductile Kirkland Lake fault (Main Break), which hosts the giant Kirkland Lake gold deposit. Three generations of fabrics formed during post-Timiskaming regional deformation events (D2, D3, and D4). A steeply dipping, east-striking S2 foliation and an east-plunging stretching L2 lineation formed during reverse-dextral slip along the Larder Lake–Cadillac deformation zone. D2 fabrics are overprinted by a north-trending S3 crenulation cleavage which formed during east-west shortening across the deformation zones. A northeast-trending steeply dipping regional S4 foliation axial planar to outcrop-scale Z-shaped F4 folds formed during northwest-southeast compression. Gold mineralization at the Upper Canada Mine along the Upper Canada deformation zone and at several occurrences along the Larder Lake–Cadillac deformation zone (e.g. Anoki and McBean properties) was emplaced during D2 and overprinted by D3 and D4. Kirkland Lake gold mineralization has a distinct metal signature (Te>Au, Mo, Pb, Ag, high Au/Ag, low As) and is probably unrelated to mineralization along the Larder Lake–Cadillac deformation zone and its splays. The gold-bearing veins of the Kirkland Lake deposit could have formed during D4, synchronously with reverse-dextral movement along the Main Break, as hydrothermal fluids associated with deep alkaline magmatism migrated to shallow crustal levels. Gold mineralization of the Narrows Break zone located approximately 350 m north of the Main Break differs in style, alteration, and geochemistry from typical Kirkland Lake gold-bearing veins and probably represents a separate hydrothermal system. Relationships between S4 and sheeted veinlets of the Narrows Break mineralized zone indicate syn-D4 timing of mineralization.

Introduction

This report summarizes results of a two-year (2003-2005) research project that was funded under the Discover Abitibi Initiative and aimed to improve understanding of geologic and structural controls of gold mineralization of the Kirkland Lake–Larder Lake gold belt (Thomson 1950). This is a roughly 3-5 km wide, approximately east-west-trending corridor extending from the village of Swastika (west of the town of Kirkland Lake) to Virginiatown (near the Ontario–Quebec border) and including parts of Otto, Teck, Lebel, Gauthier, McVittie and McGarry townships. Geologic mapping constituted the core of this project and concentrated in two areas: 26 km^2 Gauthier Township (2003) transect and 36 km^2 Teck Township transect (2004). Preliminary 1:10 000 scale geological maps P.3546–Revised (Gauthier Township transect) and P.3558 (Teck Township transect) accompany this report. Outside the transect areas, selected key outcrops were examined, and available data on structural geology and gold mineralization were reviewed.

The entire Kirkland Lake–Larder Lake gold belt is covered by high-quality 1:12 000 scale geologic maps produced in the 1930s-1940s (Thomson 1941; Thomson and Griffis 1941; Thomson 1945; MacLean 1944). A number of thematic studies that focused on various aspects of the regional geology and addressed geologic setting of gold mineralization were completed in the 1980s and 1990s. Recent geophysical surveys (e.g., OGS 2002) provided new opportunities for tracing key geologic contacts under overburden and refining regional structure. Continuing exploration for gold has generated valuable geological information, especially on the internal architecture of regional ore-controlling structures. In this report, we integrate new observations and re-evaluated existing geological data, and take into account the results of the most recent geophysical surveys and exploration programs.

The organization of this report is pre-defined by the structure of the project: two major divisions are dedicated to geology of the two transect areas. The final section summarizes main findings of the study. All structural measurements are reported in accordance with the North American right-hand-rule standard. Stereonet plots are based on the equal-area lower hemisphere projections. All location sites are given in UTM zone 17, NAD 83 coordinates.

Regional Geologic Setting of the Kirkland Lake–Larder Lake Area

GENERAL GEOLOGY

The area is part of the southern Abitibi greenstone belt of the Superior Province. The geology and tectonic evolution of the Abitibi belt are discussed in detail in Jackson and Fyon (1991) and Card (1990); only key features of the regional geological framework of the Kirkland Lake–Larder Lake area are briefly summarized here. Supracrustal rocks include submarine komatiitic, tholeiitic and calc-alkaline volcanic sequences of the Blake River (2701-2697 Ma), Kinojevis (2702-2701 Ma) and Tisdale (2710-2703 Ma) assemblages (Figure 1; Ayer et al. 2002). These form a broad east-west-trending synclinorium, the north and south limbs of which are transected by the Destor–Porcupine (north) and Larder Lake (south) regional deformation zones. Belts of clastic sedimentary and alkalic to shoshonitic rocks of the Timiskaming assemblage (2687-2675 Ma) unconformably overlie older sequences along the deformation zones. Felsic and alkalic plutons and dikes (2695-2673 Ma, Ayer et al. 2002) intrude stratified units. The rocks are metamorphosed to prehnite-pumpellyite to greenschist grade; upper greenschist and amphibolite

facies rocks are found in contact aureoles of granitoid plutons (Jolly 1978). The Kirkland Lake–Larder Lake gold belt broadly corresponds to the east-west-trending, 3-5 km wide belt of Timiskaming rocks bounded in the south by the Larder Lake–Cadillac deformation zone (Thomson 1950). The belt hosts the Kirkland Lake and Kerr Addison-Chesterville world-class gold deposits and several smaller gold deposits and occurrences. Gold mineralization is spatially associated with the Larder Lake–Cadillac deformation zone (e.g., Kerr Addison-Chesterville, Cheminis, Omega, McBean mines), and with smaller faults and shear zones proximal to the Larder Lake–Cadillac deformation zone (e.g., Kirkland Lake and Upper Canada mines). The largest gold deposit of the area, Kirkland Lake, is associated with the brittle to brittle-ductile Kirkland Lake fault ("Main Break", Todd 1928) roughly 2 km north of the Larder Lake–Cadillac deformation zone. In Québec, world-class Sigma-Lamaque, Malartic, Doyon and Bousquet gold systems and a number of smaller gold deposits occur along the Larder Lake–Cadillac deformation zone (Poulsen et al. 2000; Robert 1989); the largest lode gold deposits are associated with second- and third-order shear zones (Robert 1990).

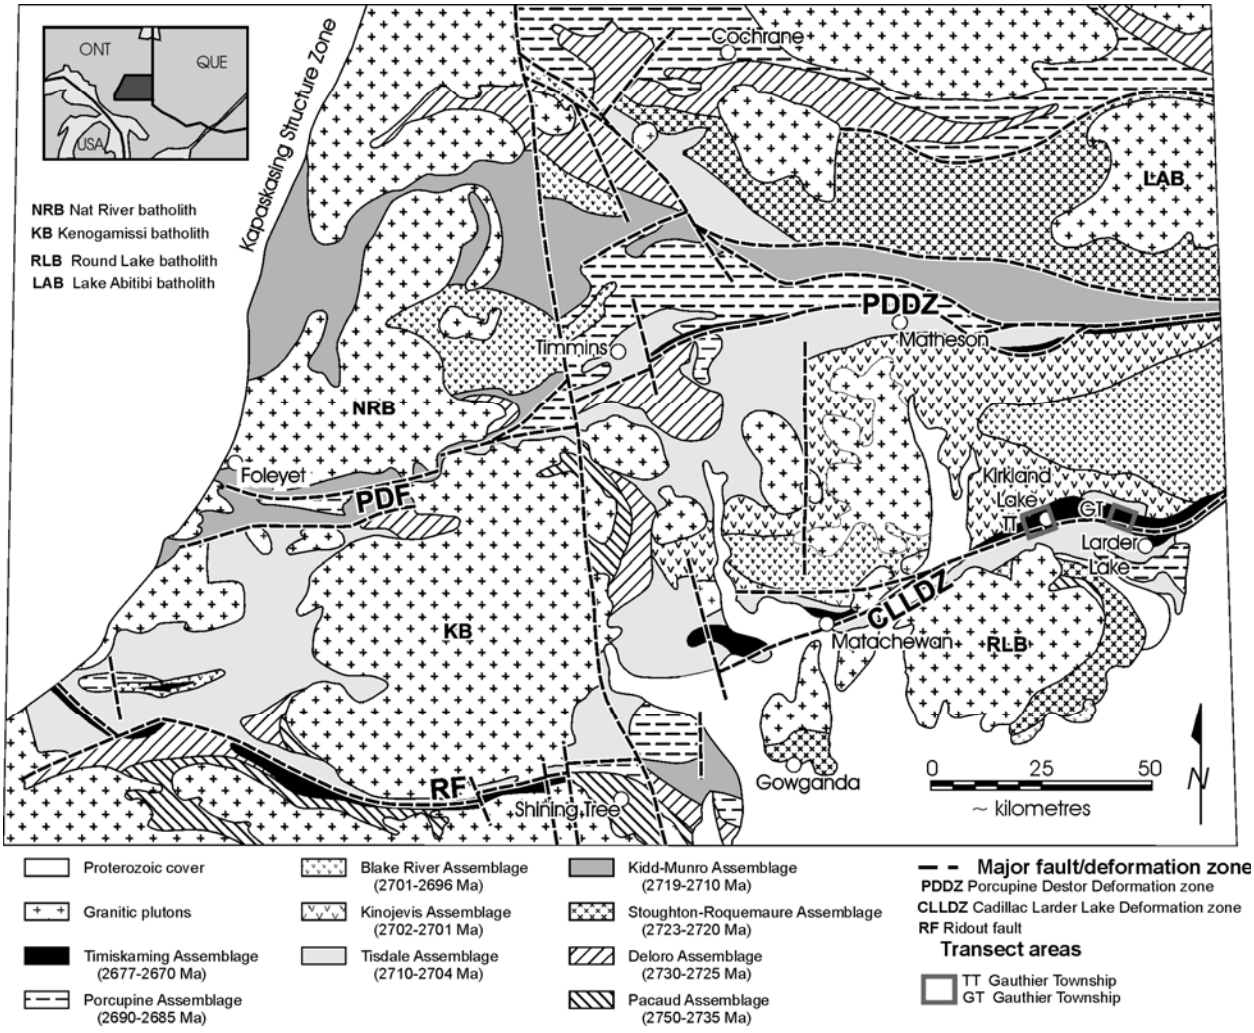

Figure 1. Regional geology showing positions of map areas (GT - Gauthier Township transect, TT - Teck Township transect; geology modified from Ayer et al. 2002).

PREVIOUS STUDIES OF REGIONAL STRUCTURAL GEOLOGY

Several authors have studied the regional structural geology of the Larder Lake–Kirkland Lake area and addressed the evolution of the Larder Lake–Cadillac deformation zone and its significance for gold mineralization (Hamilton and Hodgson 1984; Toogood and Hodgson 1985, 1986; Toogood 1986a,b; Robert 1989; Hodgson and Hamilton 1989; Hodgson et al. 1991; Smith et al. 1993; Wilkinson 1993; Wilkinson et al. 1999). The major findings and interpretations of these studies are summarized in Table 1. Original nomenclature for deformation events and corresponding fabrics is unchanged; the name Larder Lake–Cadillac deformation zone (LLDZ) is chosen of all the names suggested for this regional structure. All authors identified two major deformational fabrics in Timiskaming assemblage rocks, one of which is linked to the main stage of evolution of the Larder Lake–Cadillac deformation zone. Interpreted shear senses along the Larder Lake–Cadillac deformation zone differ significantly from author to author.

DEFINITION OF THE LARDER LAKE–CADILLAC DEFORMATION ZONE

There is a confusing interchangeable use of names for the regional ore-controlling structure. It is alternatively called the Larder Lake Break (also Kirkland Lake–Larder Lake Break, Kirkland Lake–Larder Lake–Cadillac Break, Cadillac–Larder Lake fault, etc.) or Larder Lake–Cadillac deformation zone (also Cadillac–Larder Lake shear zone, Kirkland Lake–Larder Lake deformation zone, etc.). Originally, the term "Larder Lake Break" (e.g., Thomson 1941; Thomson and Griffis 1941) was applied to a discrete (up to 100-500 feet wide) band of strong shearing and carbonatization at the contact between Timiskaming sedimentary rocks and older mafic volcanics. Weakly carbonatized segments of the Break were documented to contain talc-chlorite schists (Thomson 1941). Most economic gold deposits of the Larder Lake area are spatially associated with the Larder Lake Break (Thomson 1941; Thomson and Griffis 1941).

Hamilton and Hodgson (1984), Hamilton (1986), Toogood and Hodgson (1985) and Toogood (1986b) recognized that deformational fabrics related to this tectonic zone extend over a much wider area (e.g., 2-3 km, Toogood and Hodgson 1985). Hamilton and Hodgson (1984) used the term "Kirkland Lake–Larder Lake deformation zone" to define this wider corridor of variably deformed rocks enveloping the more narrow "Kirkland Lake–Larder Lake Break". Similarly, Robert (1989) defined a 200-750 m wide Cadillac tectonic zone that includes a discrete, up to 50 m wide, Cadillac Break. More recently, Wilkinson et al. (1999) defined the Larder Lake–Cadillac deformation zone as a 10-50 m wide high-strain zone separating the Timiskaming and Hearst assemblages from the older Larder Lake and Boston assemblages, thereby interchanging the original term "Break" with the term "deformation zone".

We recognize that the terms "Break" and "deformation zone" have different meanings and should not be used interchangeably. We use the term "Larder Lake Break" in the original meaning of Thomson (1941) and Thomson and Griffis (1941). Larder Lake Break is a single or branching 10 m to approximately 150 m wide high-strain zone traced from the Kerr Addison-Chesterville deposit (McGarry Township) to the Anoki property (Gauthier Township). It generally corresponds to the contact of Timiskaming and Tisdale assemblages, although local settings of the structure vary. Commonly the Break is marked by bands and lenses (faulted slivers?, Hodgson et al. 1991) of variably carbonatized and locally silicified ultramafic talc-chlorite schists. The Larder Lake–Cadillac deformation zone is a wider structure that is defined by intensity of deformation and development of pervasive fabrics. In the two areas mapped in this project, the Larder Lake–Cadillac deformation zone is 200 to 500 m wide; it commonly encompasses several lithotectonic units and does not have sharp geologic boundaries. The Larder Lake Break (in the original meaning of Thomson 1941) is a major discontinuity within the Larder Lake–Cadillac deformation zone.

Table 1. Overview of structural geological studies of the Kirkland Lake–Larder Lake gold area.

Author	First generation fabrics/structures	Second generation fabrics/structures	Regional stress field, LLDZ sense of movement	Relative timing of gold mineralization
Hamilton and Hodgson (1984)	S1: W-NW trending cleavage axial planar to W-NW trending folds (e.g., Spectacle Lake anticline)	S2: NE (040-060)- trending steeply dipping crenulation cleavage.	D1: N-NE (later N-S) compression, oblique sinistral movement on LLDZ D2: NW-SE compression, dextral movement on LLDZ	Late in deformation history
Toogood and Hodgson (1985)	S1: foliation mirrors strike of LLDZ, typical orientation 070-090. Axial planar to steeply plunging isoclinal folds. Stretching lineation (L1) plunging: NE-E, and S-SE, north and south of LLDZ, respectively.	S2: constant 040-070 strike, subvertical dip	LLDZ: early sinistral strike-slip (D1), later transpression with dextral strike-slip	Late in strain history
Toogood and Hodgson (1986)	C-S foliations within the LLDZ	Subvertical NE-trending foliation: result of progressive expansion of LLDZ	Dextral strike-slip movement in LLDZ, expansion in width with progressive displacement	
Toogood (1986a)	C-S foliation within the LLDZ	Subvertical NE-trending foliation overprints C-S fabrics in LLDZ	Dextral strike-slip movement on LLDZ	
Toogood (1989)	Early E-NE to SE trending fabric parallel to LLDZ, common S-C fabrics	Steep NE-trending foliation axial planar to M and Z-folds. Gradual change into subparallel orientation with the earlier fabric in LLDZ. Related to dextral strike-slip movement in a laterally expanding shear zone.	Dextral strike-slip movement, progressive lateral expansion of LLDZ	Upper Canada gold deposit within the Upper Canada deformation zone: 3 penetrative fabrics; the earliest correlates to the early regional fabric. Gold mineralization postdated the earliest fabric, and was modified (structurally and hydrothermally) during the latest deformation phase.
Hodgson and Hamilton (1989)	Pre-Timiskaming D0: folds with no foliation. Post-Timiskaming D1: foliation axial planar to WNW-ESE trending folds, parallel to LLDZ and rotated to LLDZ	D2: typically Z-asymmetric folds, axial planar foliation overprinting D1 fabrics. D2 foliation rotates into parallelism with D1 fabric near LLDZ.	D1: NNE-SSW compression, oblique thrusting (N over S), no major strike-slip D2: NW-SE compression, S over N backthrusting	Gold mineralization related to final stages of D2

Author	First generation fabrics/structures	Second generation fabrics/structures	Regional stress field, LLDZ sense of movement	Relative timing of gold mineralization
Robert (1989) (Cadillac Tectonic zone, Val d'Or area, Québec)	S1 striking 070-090, oblique to EW-striking Cadillac Tectonic Zone	S2: NE-SW to E-W –trending spaced crenulation cleavage axial planar to Z-asymmetric folds	EW-striking segment of the Cadillac Tectonic Zone: zone of dextral transpression. D1: N-S shortening, subvertical stretching, local dip-slip movements, synchronous dextral shearing; D2: dominantly transcurrent dextral shear, some shortening.	
Hodgson et al. (1991)	S1: E-W to WNW-ESE striking foliation axial planar to upright, tight to isoclinal folds. Parallels the orientation of LLDZ, variably overprinted by S2	S2: E-W to ENE-WSW trending, steeply dipping foliation. Gauthier Tonwnship: in about 100 m north of LLDZ bends into parallelism to LLDZ.	LLDZ in Gauthier Township: pre-D1 normal fault (?) D1: thrust fault; D2: oblique reverse-dextral movement (S side up).	Gold mineralization is closely associated with D2 structures (e.g., Kirkland Lake Main Break is a D2 structure).
Smith et al. (1993)	Similar to Hamilton and Hodgson (1984)	Similar to Hamilton and Hodgson (1984)	Sense of movement varies along the LLDZ depending on an orientation of a given segment relative to principal compression direction (D1: N-S to NNE-SSW; D2 : NNW-SSE to NW-SE).	Gold mineralization at Kerr Addison Mine is synchronous to late phases of ductile deformation in LLDZ (i.e., syn-D2).
Wilkinson et al. (1999)	S2 parallels the LLDZ: strike varies from 090 (east-west striking segments) to 085 (northeast-striking segments), and 110 (southeast-striking segments)	S3: subvertical pervasive NE-striking (055-070) crenulation cleavage axial planar to symmetric to Z-asymmetric folds. Locally deflected into parallelism with S2.	D2: N-S shortening; E-W - trending segments of LLDZ accumulate bulk coaxial strain, NE and SE-trending segments experience sinistral and dextral transpression, respectively. Some reverse (S over N) component. D3: NW-SE shortening, dextral reactivation of SE and EW-oriented segments of LLDZ.	

Gauthier Township Transect

GENERAL GEOLOGY AND ROCK TYPES

The Gauthier Township transect (Figures 2 and 3, Map P.3546–Revised, back pocket) is located west of the town of Larder Lake and north of Highway 66. The area comprises Archean mafic and ultramafic volcanic rocks of the Larder Lake Group of the Tisdale assemblage (Jackson 1995; Ayer et al. 2002), alkalic volcanic rocks and clastic sedimentary rocks of the Timiskaming assemblage, and intermediate to felsic volcanic rocks of the Gauthier Group (Tisdale assemblage; Ayer et al. 2002). Volcanic rocks of the Larder Lake Group are exposed in the southern part of the map area along Highway 66; they also form a 250 m wide band between the McBean open pit and Dobie townsite. Along Highway 66, the Larder Lake Group consists of variolitic massive and pillowed basalts with subordinate ultramafic talc-chlorite and (chlorite)-carbonate-fuchsite schists. This predominantly basaltic sequence contains 0.1 to 15 m thick beds of siliceous, locally graphitic, interflow exhalites. Volcanic rocks host gabbroic intrusions composed of plagioclase and coarse-grained (3 mm to 1-2 cm in length) prismatic amphibole possibly replacing primary pyroxene. The band of Larder Lake volcanic rocks north of the McBean pit probably represents a fault-bounded slice. It consists predominantly of pervasively foliated chlorite-rich rocks with no recognizable primary flow textures, and contains discontinuous lenses of ultramafic carbonate-fuchsite schists. Geochemically, foliated chloritic rocks are similar to pillow basalts from the Anoki area (immediately south of the Larder Lake Break) and most likely represent strained basaltic lavas or tuffs. Both pillowed basalts and chlorite schists plot in the tholeiite field of the AFM diagram and, apart from altered rocks of the gold-bearing Anoki zone, in the high-Fe-tholeiitic basalt field of the Jensen cation plot (Figure 4). High MgO (20-25%), Cr (about 1900-2800 ppm) and Ni (about 800-1300 ppm) contents of talc-chlorite and carbonate-fuchsite schists indicate a komatiitic protolith. Felsic to intermediate tuffs and tuff breccias of the Gauthier Group (Tisdale assemblage of Ayer et al. 2002) underlie the northern part of the map area. A 2700±3 Ma U-Pb age of the Gauthier Group was previously reported by Corfu (1993).

Most of the map area consists of Timiskaming volcanic and sedimentary rocks. The sedimentary rocks include two major units. The first unit (unit 1, Figure 2) is located immediately to the north of the Larder Lake Group in the McBean open pit area. It consists of largely non-graded sandstones, highly strained polymictic conglomerates, and minor interbeds and lenses of chlorite schists. In most surface outcrops in the southeast of the map area, the rocks are carbonate-altered and oxidized. The least altered and unweathered sections are from Queenston Mining Inc. drill core from the area west of the McBean pit. There, the unit consists largely of greenish-grey to green sandstones with chlorite-rich matrix. Strained conglomerates constitute 20 to 60 volume % of the unit. Most pebbles are carbonatized and stretched into ribbons and bands; only clasts of leucocratic granitoids, minor porphyries, chert, jasper and quartz, which are both resistant to carbonatization and rheologically competent, survived the intense deformation.

The second sedimentary unit (unit 2, Figure 2) underlies the east-northeastern portion of the map area. It consists of graded grey to greenish-brownish-grey turbiditic sandstone, siltstone and subordinate argillite interlayered with few 10-60 m wide conglomerate horizons. In general, these conglomerates have a higher clast-to-matrix ratio compared to conglomerates in unit 1, perhaps due to lower strain. Feldspar-phyric igneous rocks constitute the most abundant clast type in the conglomerates. A U-Pb detrital zircon sample of turbiditic sandstone analyzed in this study returned a maximum age of 2677.7 ± 3.1 Ma (Ayer et al. 2005). This date indicates that turbidites previously thought to predate Timiskaming sedimentation

(e.g., Corfu et al. 1991; Jackson 1995; Mueller et al. 1994) belong to the Timiskaming assemblage. In addition to the two major clastic units, smaller units of volcaniclastic sandstones and polymictic conglomerates are associated with Timiskaming volcanic rocks in the western and northern parts of the map area.

Alkalic volcanic rocks of the Timiskaming assemblage occupy the central and east-northeast parts of the map area. North of the Upper Canada Mine, volcanic rocks are represented mainly by massive plagioclase-amphibole-phyric lavas and breccias. The latter consist of angular to subrounded fragments (1-2 cm to 20-30 cm) of brown, reddish-brown and green feldspar-phyric rocks enclosed in a dark green chloritized matrix. Transitions from breccias to massive and flow-banded feldspar-phyric lavas are observed at several localities. Strongly deformed and hydrothermally altered aphanitic tuff and tuff breccia are exposed in stripped outcrops west of the Upper Canada shaft #2. Between the Upper Canada Mine and Dobie townsite, the volcanic rocks consist of intermingled lavas, tuffs and breccias, including pseudoleucite- and pyroxene-bearing varieties. A sample of massive feldspar-phenocryst-rich lava collected approximately 600 m southeast of the former Upper Canada shaft #1, returned a U-Pb zircon age of 2669.6 ±1.4 Ma (Ayer et al. 2005).

West-northwest of the McBean open pit, the southern contact of the volcanic rocks with Timiskaming clastic rocks was intersected by drill holes and traced for roughly 1000 m along strike by Queenston Mining Inc. At the contact, the volcanic rocks are represented by foliated brown to brownish dark grey, largely aphyric lavas (?), which locally contain thin prismatic to acicular amphibole or, less commonly, feldspar laths that are 1-3 mm long. East of Dobie, a separate unit of volcaniclastic breccia, up to 300 m wide, is bounded by Timiskaming sedimentary rocks on the north, south and east. The breccia consists of rounded and angular clasts of pink and reddish-brown, green and white aphanitic and feldspar-phyric volcanics surrounded by a green to greenish-grey matrix. Drilling by Queenston Mining Inc. west of the McBean open pit intersected narrow horizons of tuffs (?) enclosed in conglomerates and sandstones. In addition to being lithologically distinct, these tuffs are notably more magnetic than the sedimentary rocks. Patterns on aerial magnetic maps show that these horizons may constitute the westward continuation of the Timiskaming volcaniclastic unit exposed east of Dobie.

In the east of the map area, there is another large unit of Timiskaming volcanic rocks consisting of massive aphyric and amphibole-phyric lavas and breccias, which are somewhat similar to those exposed north of the Upper Canada Mine. Hyde (1978) named this unit the Bear Lake Formation. It has a U-Pb zircon age of 2677 ± 2 Ma (Corfu et al. 1991). On previously published maps (Thomson and Griffis 1941; Jackson 1995) this unit terminates abruptly south of Little Larder Lake along an east-west-trending contact with the Gauthier Group. Our mapping does not confirm this. Volcanics exposed immediately south and southwest of Little Larder Lake are Timiskaming amphibole-phyric lavas that differ macroscopically and geochemically from the Gauthier Group volcanic rocks. Further west, the along-strike continuation of this unit under fluvio-glacial overburden is marked by a roughly 300 m wide, west-northwest-trending (approximately 290º) magnetic high that can be traced for about 4 km west of Little Larder Lake on airborne magnetic maps (Figure 3). To the east-southeast, the unit extends to the eastern boundary of McVittie Township (Thomson 1941; Thomson and Griffis 1941).

Several generations of intrusive rocks crop out in the area. They include gabbro stocks and sills spatially associated with the Larder Lake basalts; stocks and dikes of quartz-feldspar porphyry, feldspar porphyry, trachyte and syenite porphyry and biotite lamprophyre of probable Timiskaming age; and Early Proterozoic Matachewan diabase dikes.

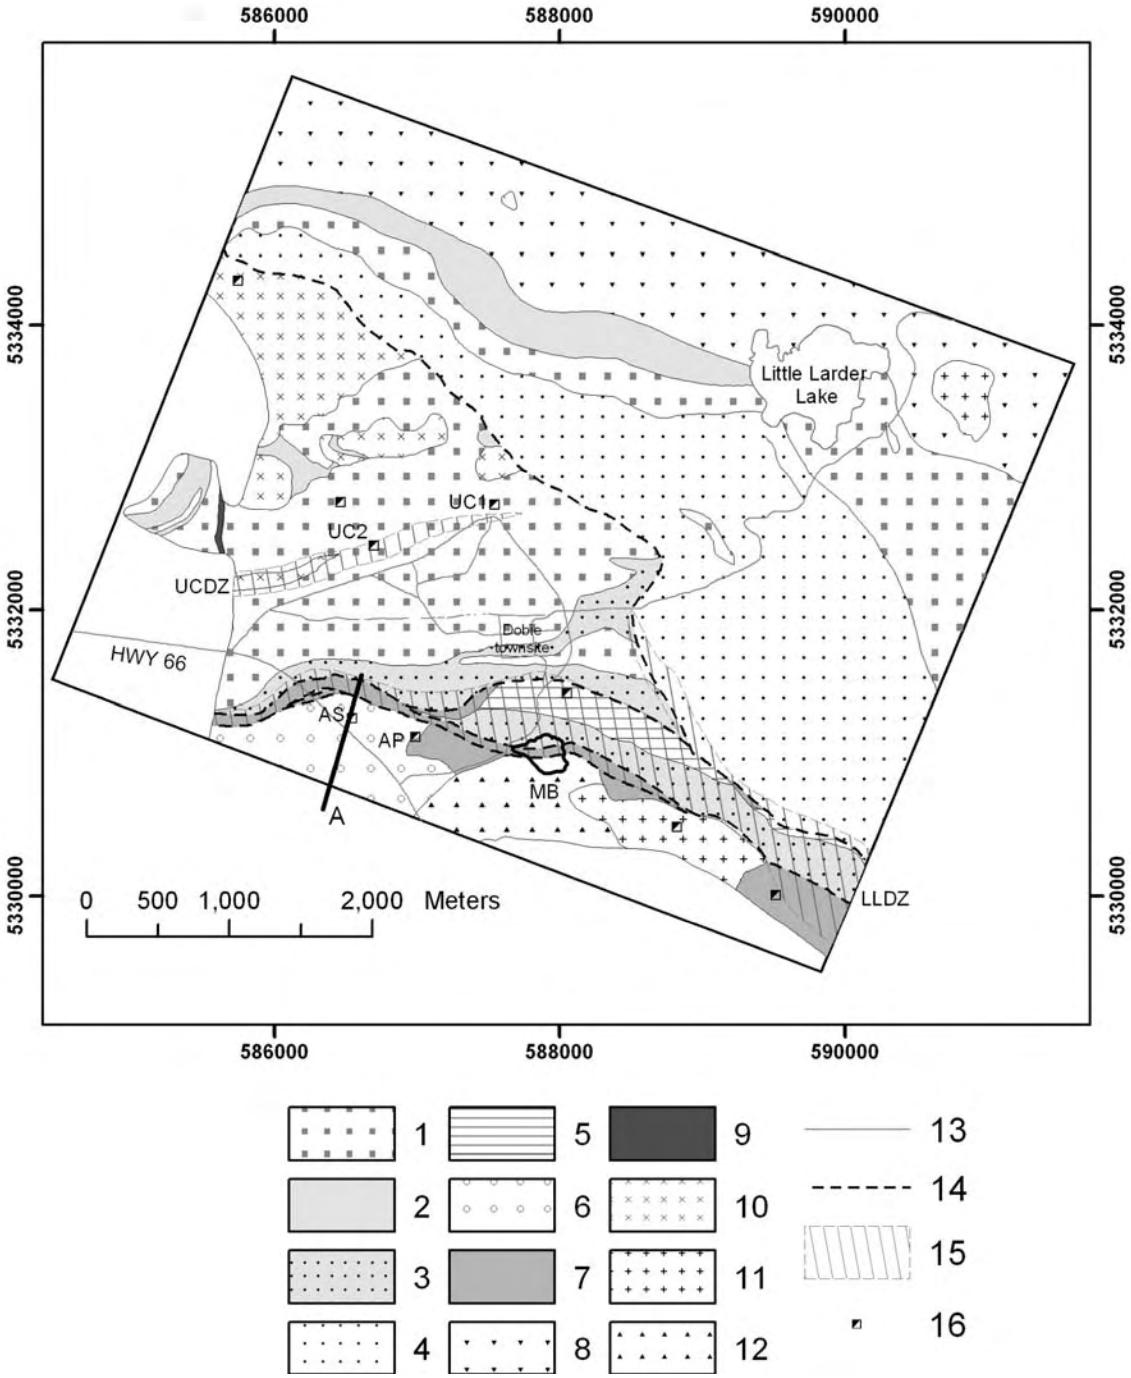

Figure 2. Generalized geological map of the Gauthier Township transect area. 1-4, Timiskaming assemblage: 1-volcanic rocks, 2-volcaniclastic sandstones and conglomerates, 3-sandstones and conglomerates (unit 1), 4-turbidites (unit 2); 5-7, Larder Lake Group (Tisdale assemblage): 5-mafic volcanic rocks (chlorite schists), 6-mafic volcanic rocks (massive, variolitic and pillowed flows), 7-ultramafic volcanic rocks; 8-Gauthier Group (Tisdale assemblage) felsic to intermediate tuffs and tuff breccias; 9-diabase dikes; 10-syenite porphyries; 11-quartz-feldspar porphyries; 12-gabbro; 13-contacts; 14-faults; 15-deformation zones (LLDZ-Larder Lake–Cadillac; UCDZ-Upper Canada); 16-shafts (UC1,2-Upper Canada shafts 1 and 2; AS and AP-Anoki shaft and ramp portal); MB-McBean open pit. Thick line labeled "A"- approximate location of cross-section shown in Figure 18A.

DEFORMATION ZONES

The most significant structural feature in the area is the southeast-northwest-striking Larder Lake–Cadillac deformation zone, the high-strain zone along the contact between the Timiskaming assemblage and Larder Lake Group (Tisdale assemblage). The zone is defined by the intensity of the deformation and does not have sharp geological boundaries. Near the eastern border of the map area, the estimated width of the high-strain zone is about 500-600 m. Further west, in the poorly exposed area between the McBean pit and Upper Canada Mine, identifying the boundaries of the zone is more difficult, because of rather poor exposure and, perhaps more importantly, because a strong foliation occurs continuously between the Larder Lake–Cadillac and the Upper Canada deformation zones. A 20 to 150 m wide band of highly strained ultramafic talc-chlorite and carbonate-fuchsite schists, traditionally referred to as the Larder Lake Break (Thomson and Griffis 1941), constitutes the southern flank of the Larder Lake–Cadillac deformation zone. Numerous felsic and syenitic dikes intrude the schists. Sketches of the east wall of the McBean open pit by Bell (1987) indicate that texturally variable dikes make up about 50-60% of this unit. Surface mapping and exploration drilling reveal the rather complex internal makeup of the Larder Lake–Cadillac deformation zone. In the McBean pit area, the deformation zone encompasses three lithotectonic units (from south to north): a 50-70 m wide band of ultramafic talc-chlorite and carbonate-fuchsite schists ("Larder Lake Break", Thomson and Griffis 1941); a 150-200 m wide unit of Timiskaming conglomerates and sandstones; and a 250 m wide lens of chlorite schists of the Larder Lake Group. The north contact of this mafic volcanic unit and Timiskaming sedimentary rocks is informally called "the North Break". Immediately to the west, in the Anoki area, the south boundary of the Larder Lake–Cadillac deformation zone broadly corresponds to a northeast-striking (065-070º) and shallowly (approximately 35-40º) dipping fault informally called the "South Splay" by Queenston Mining Inc. geologists (see additional discussion in the "Gold Mineralization" section).

The northeast-striking (approximately 070º) Upper Canada deformation zone is the second largest high-strain zone in the map area; it probably represents a northern splay of the Larder Lake–Cadillac deformation zone (Toogood 1989). The rocks between Upper Canada and Larder Lake–Cadillac deformation zones are pervasively foliated. Further north, the envelope of foliated rocks extends for 400-500 m from the Upper Canada deformation zone. The Upper Canada deformation zone itself is poorly exposed. Strippings west of the former Upper Canada Mine shaft #2 provide a fragmental exposure of the high-strain zone over a distance of about 150 m across strike and roughly 400 m along strike. East and west of this location, the deformation zone is covered by overburden. The western continuation of the deformation zone was reportedly traced by drilling for about 5 km, to its junction with the Larder Lake–Cadillac deformation zone (Toogood 1989). Where it ends to the east is less clear. About 1.5 km east of former shaft #2, the 070º trending deformation zone is expected to transect the magnetically distinct contact between Timiskaming volcanic rocks (west) and turbidites (east). Patterns on aerial magnetic maps do not show major displacement of the contact (Figure 3).

DEFORMATIONAL FABRICS

There are 4 generations of deformational fabrics in the Timiskaming rocks. The earliest post-Timiskaming fabric is designated S2 following Wilkinson et al. (1999). This assignment of the earliest post-Timiskaming fabric to the second deformation event is based on the recognition of an earlier deformational pulse (D1) that produced large-scale folds and thrusts without penetrative fabrics (Wilkinson et al. 1999; Corfu et al. 1991). Wilkinson et al. (1999) and Corfu et al. (1991) interpreted this early event as pre-Timiskaming; our new data suggest otherwise. In the eastern part of the map area, we mapped younging reversals in northwest-striking, northeast-dipping turbidites (Figure 5). The oldest deformational fabric, S2, is consistently oriented counterclockwise to the northeast- and southwest-facing

beds. This geometry implies that the rocks were folded during an early event that must be younger than the maximum depositional age of turbidites (2677 Ma).

S2 is the earliest regional fabric, and the main foliation of the Larder Lake–Cadillac and Upper Canada deformation zones. It is defined by flattened clasts in sedimentary and volcanic rocks, and by a penetrative schistosity and compositional banding of secondary chlorite, talc, white mica, fuchsite and carbonate in hydrothermally altered rocks (Photo 1). Figures 6 and 7 illustrate the variations in the orientation of S2. Within the Larder Lake–Cadillac deformation zone (area 1, Figures 6 and 7), S2 generally strikes east-southeast (095-120º) and dips steeply (70-80º) south, roughly parallel to the estimated trend and dip of major lithological contacts in the deformation zone. In the northeast-trending Upper Canada deformation zone, immediately north of it, and between the Upper Canada and Larder Lake–Cadillac deformation zones (area 2, Figures 6 and 7), S2 is steeply dipping and northeast-striking (060-085º). In Timiskaming turbidites (area 3, Figures 6 and 7), S2 strikes 275º to 330º and dips steeply to moderately northeast. It is oriented either parallel to or 5º-20º counterclockwise to bedding (bedding orientation is shown in Figure 8). Relatively rare, open to isoclinal outcrop-scale folds with axial planar S2 occur in turbidites (Photo 2). A well-developed lineation (L2) is associated with S2 throughout the map area. L2 is defined by secondary mineral aggregates (mineral lineation), stretched clasts in conglomerates and volcanic rocks (Photo 2), and varioles in basalts (stretching lineation). L2 plunges moderately to steeply (35º-60º) to the east throughout the map area (Figure 6, Photo 3).

A second foliation, S3, overprints S2 in the Upper Canada deformation zone and several other locations in the map area. S3 is a steeply-dipping, north- and west-northwest-trending, crenulation cleavage (Figure 9) defined by darker, sericite- and chlorite-rich domains (0.5-3 mm wide) separating typically wider (3-10 mm) feldspar-carbonate-quartz domains in which S2 is finely crenulated (Photo 4). The morphology and orientation of S3, as well as its relationships with other fabrics are described in more detail in the section on the geology of the Upper Canada Mine.

S4 is a steeply dipping, northeast-trending (060º-080º, Figure 9) regional cleavage. It is axial planar to outcrop-scale Z-shaped and, more rarely, symmetric folds. Locally, cleavage changes orientation to E-W and even east-southeast, due to deflection along narrow high strain zones. However, on a regional scale, the orientation of S4 is relatively constant, and there is no systematic change in the orientation of S4 with increasing or decreasing distance to the Larder Lake–Cadillac deformation zone. Most typically, S4 is a discrete crenulation cleavage axial planar to microfolded bedding and S2 (Photos 5, 6, and 7). The development of the cleavage was typically accompanied by notable pressure solution removal of material from the limbs of the microfolds (Photo 7).

S5 is a late crenulation cleavage, trending 130º to 170º and dipping 30º to 80º W (Figure 9). It is observed mainly in the Larder Lake–Cadillac deformation zone, in the eastern part of the map area. It overprints all other fabrics, and is commonly axial planar to S-shaped folds of S2. No map-scale structure is associated with this fabric. The regional significance of S5 is at present unclear and it is not further discussed in this report.

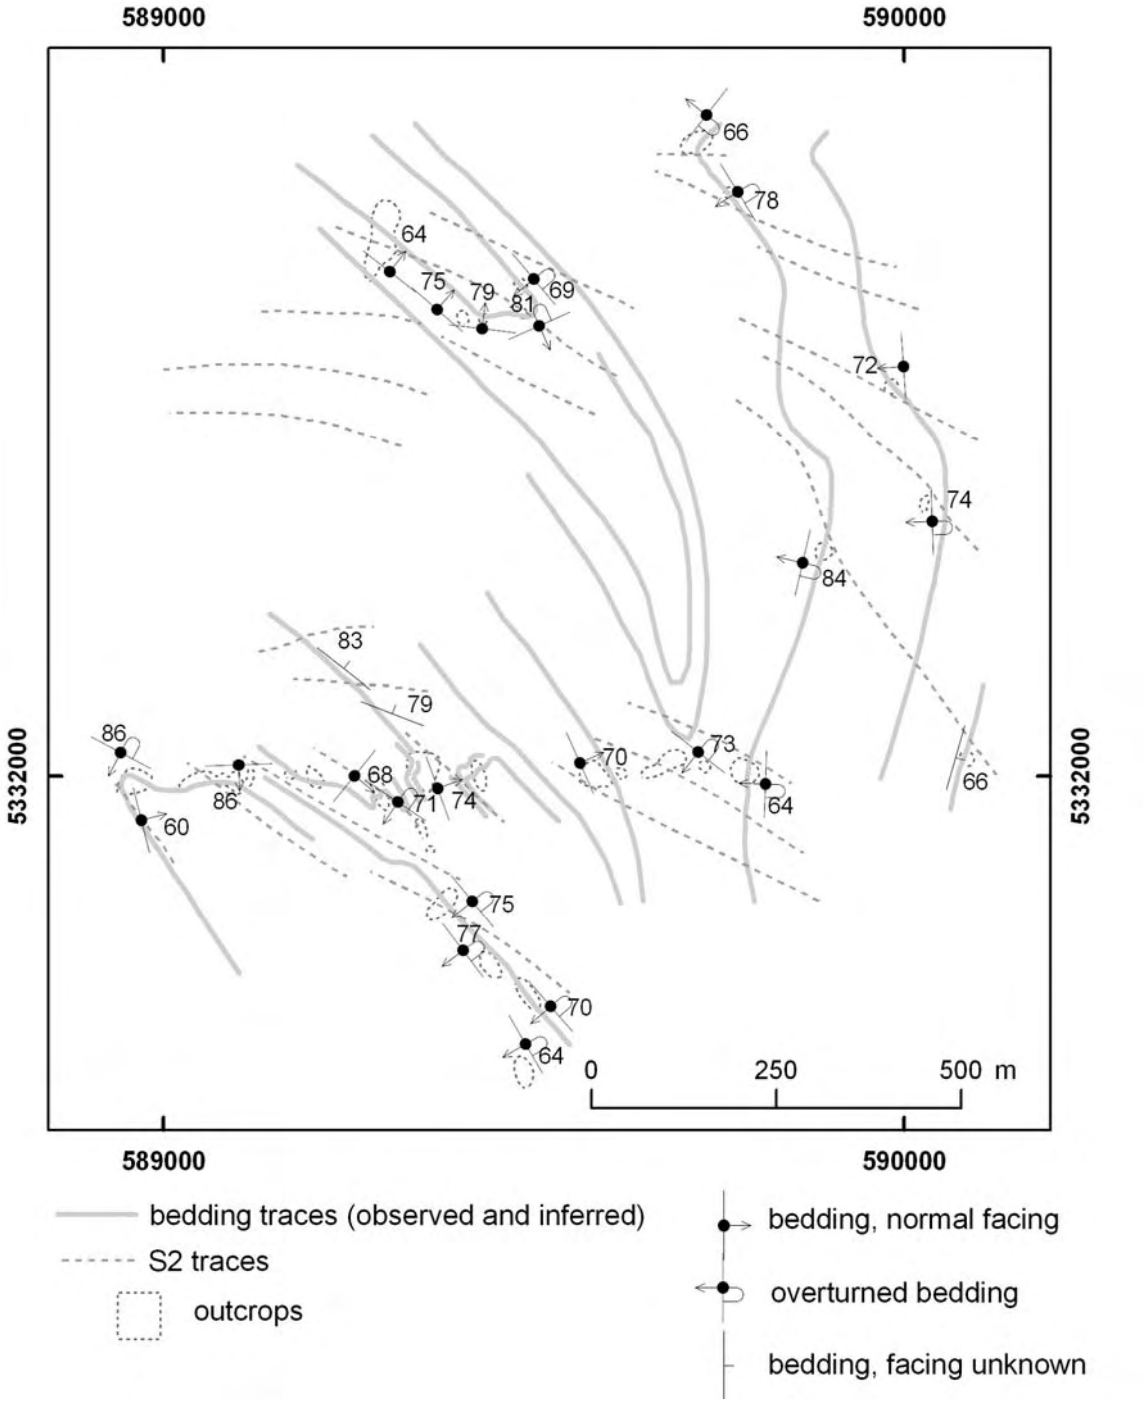

Figure 5. Relationships between bedding reversals and S2 in Timiskaming turbidites. Interpreted bedding traces are shown with some generalization. Note consistent counterclockwise orientation of S2 with respect to bedding (regardless of facing direction). This indicates that bedding reversals could not have resulted from D2 folding and probably reflect earlier folding event. (Data shown in this figure were processed after Map P.3546–Revised was finalized, and are not shown on the map.)

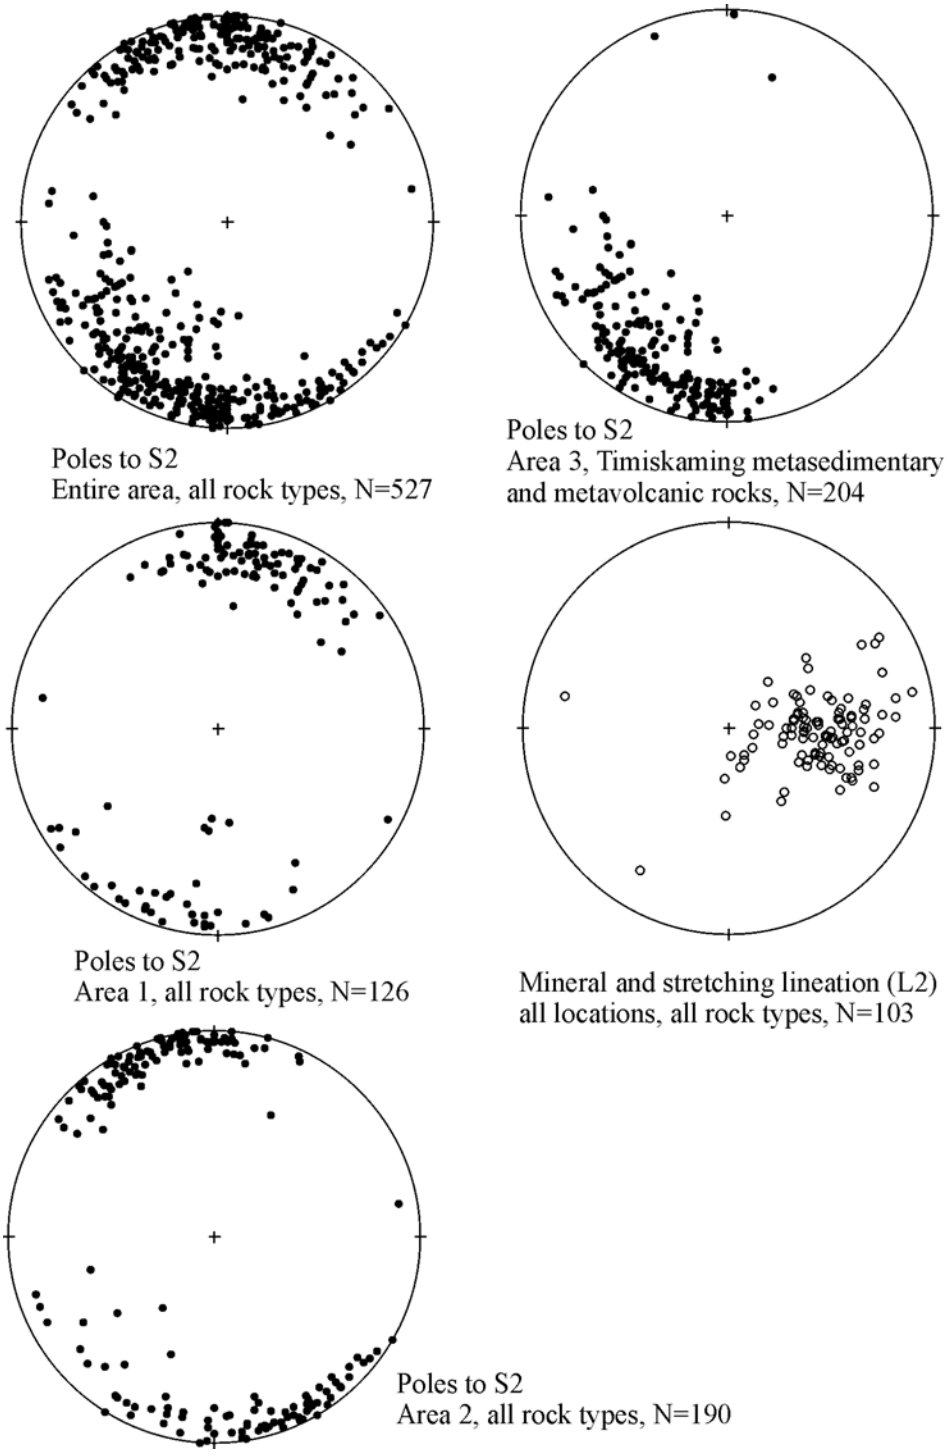

Figure 6. Stereonet plots of S2 and L2 (data collected during detailed mapping of Upper Canada stripped outcrops are not included).

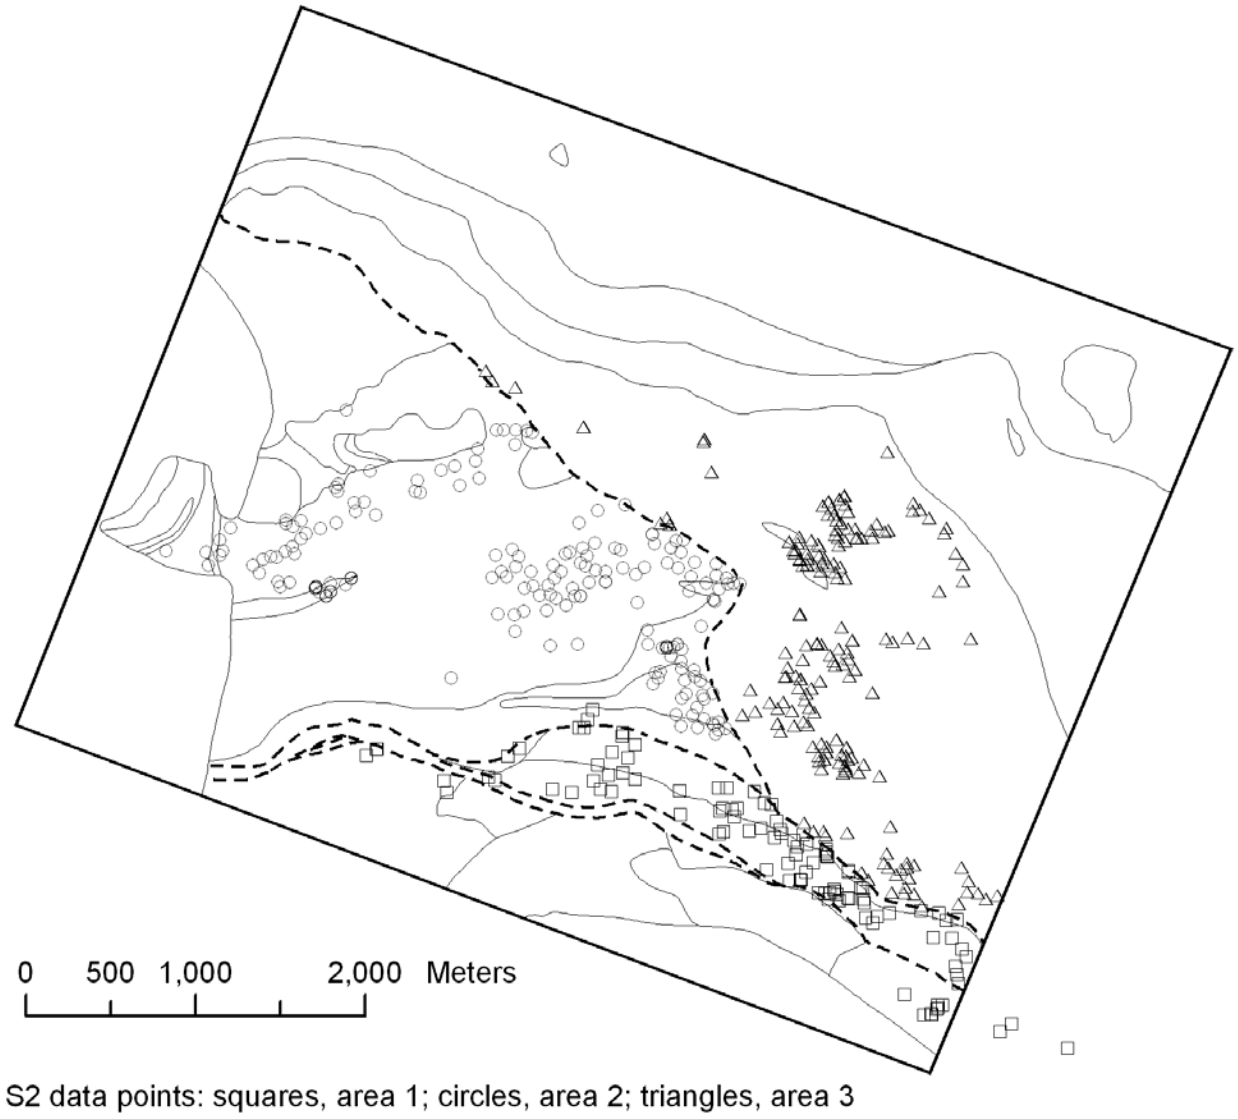

Figure 7. S2 data points from areas 1, 2, and 3.

Photo 1. Foliation (S2) defined by compositional banding, and stretching lineation (L2) in highly strained Timiskaming conglomerates. Lineation is marked by pebbles stretched into ribbons (e.g., the upper part of the photo). Plane of view is perpendicular to foliation and approximately parallel to stretching lineation. Marker pen (roughly 15 cm) for scale. North wall of flooded McBean open pit.

Photo 2. F2 fold in Timiskaming turbidites: bedding (solid line) is folded with axial planar S2 (thin dashed line, east-west) and is overprinted by S4 (thick dashed line, northeast-southwest). Pencil (15 cm) for scale.

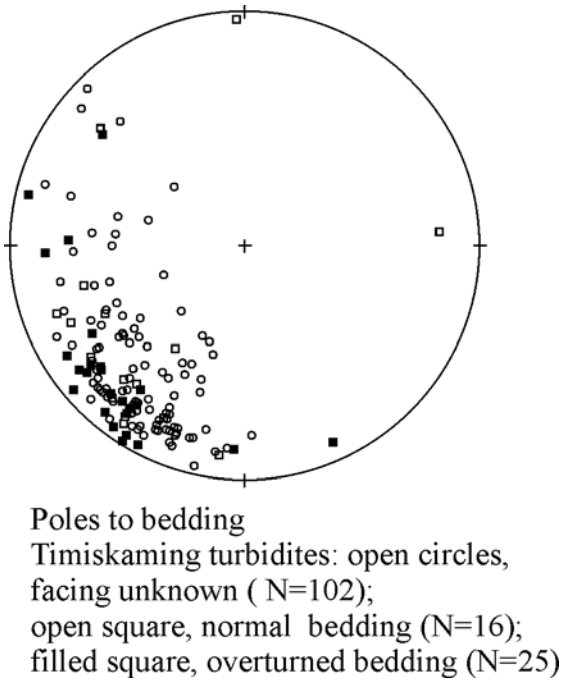

Figure 8. Stereonet plot of bedding in Timiskaming turbidites.

Photo 3. Stretching lineation (L2) in volcaniclastic breccias east of Dobie townsite. Lineation plunges approximately 45-50º east. Pencil (15 cm) for scale.

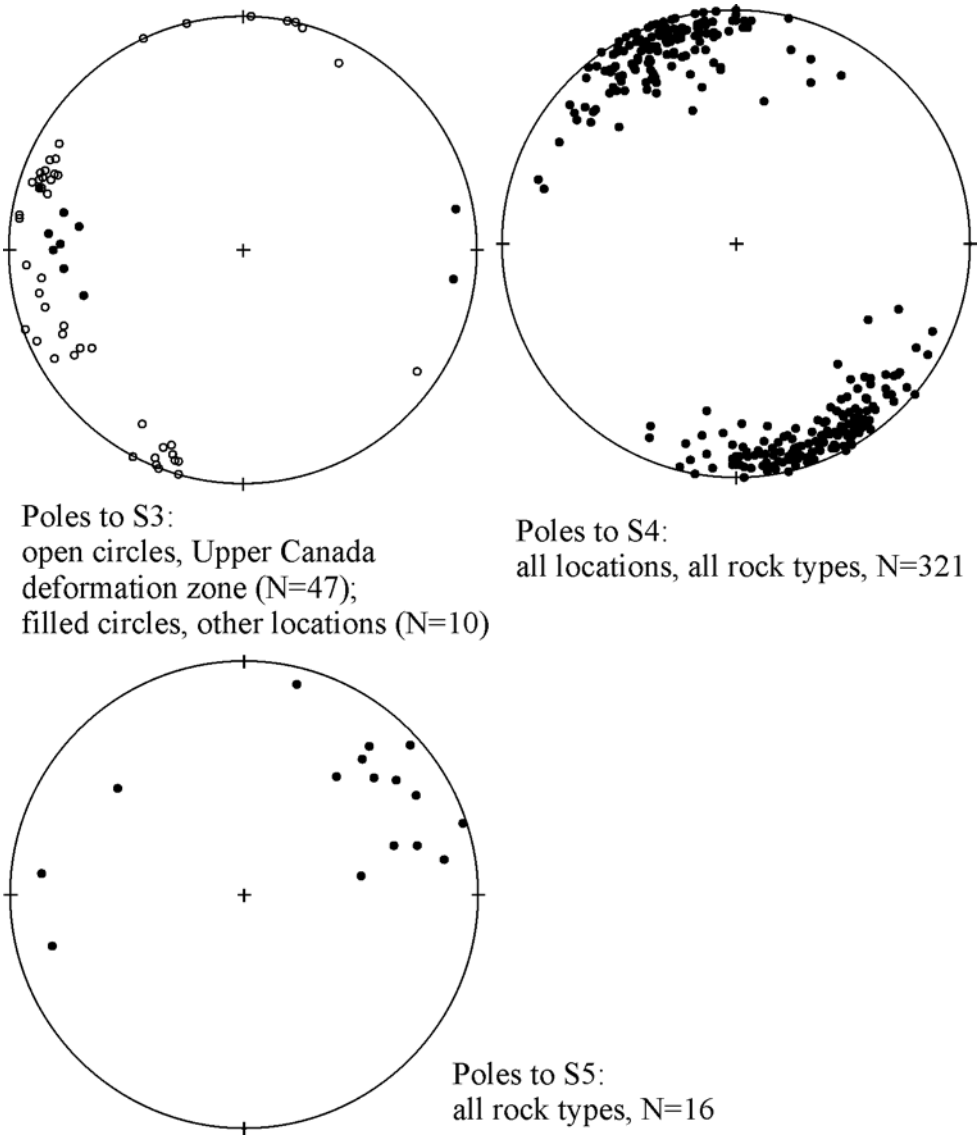

Figure 9. Stereonet plots of S3, S4, and S5 (S4 data collected during detailed mapping of Upper Canada stripped outcrops are not included).

Photo 4. S3 crenulation cleavage (parallel to the pencil) overprinting S2 (oriented approximately east-west, crenulated). Upper Canada L-W stripping. Pencil (15 cm) for scale.

Photo 5. Crenulation cleavage S4 (northeast-southwest) overprinting S2 in altered felsic dike. Coin diameter 1.8 cm.

Photo 6. Discrete crenulation cleavage S4 in Timiskaming turbidites.

Photo 7. Photomicrograph (plane polarized light, field of view approximately 5 mm) of S4 in Timiskaming siltstone-argillite (darker layer in the bottom half of the photo is finer and more phyllosilicate-rich). Discrete crenulation cleavage S4 (thin dark seams) overprints bedding and bedding-parallel S2. Note tighter spacing of discrete cleavage planes in finer, phyllosilicate-rich rock and an apparent sinistral offset of a thin quartz-rich interbed (marked by white arrows) due to pressure solution along cleavage planes.

KINEMATIC INDICATORS IN THE LARDER LAKE–CADILLAC DEFORMATION ZONE

Asymmetric shear-sense indicators were observed at two localities along the Larder Lake–Cadillac deformation zone. The first location is along the southern flank of the deformation zone at the contact between Timiskaming conglomerate and a band of ultramafic schists that separates Timiskaming clastic rocks from mafic volcanics of the Larder Lake Group and associated gabbroic intrusions (i.e., Larder Lake Break, after Thomson and Griffis 1941). Highly strained Timiskaming conglomerates with well-developed stretching lineation (L2) are exposed in the northern wall of the flooded McBean open pit. On the surface that is parallel to L2 and perpendicular to S2, some of the least strained pebbles show asymmetric pressure shadows indicating oblique reverse-dextral slip (south side over north and to the west) along the direction of stretching lineation (Photo 8).

The second location is at the northern margin of the Larder Lake–Cadillac deformation zone (stripped outcrop at the Princeton Property, eastern part of the area). Here, shear-sense indicators include a combination of dextral Z-shaped drag folds, the clockwise orientation of extensional quartz-carbonate veins with respect to foliation (S2), and offsets of these veins along S2. The interpreted slip direction is similar to that documented at the McBean pit; that is, oblique reverse-dextral slip parallel to the stretching L2 direction.

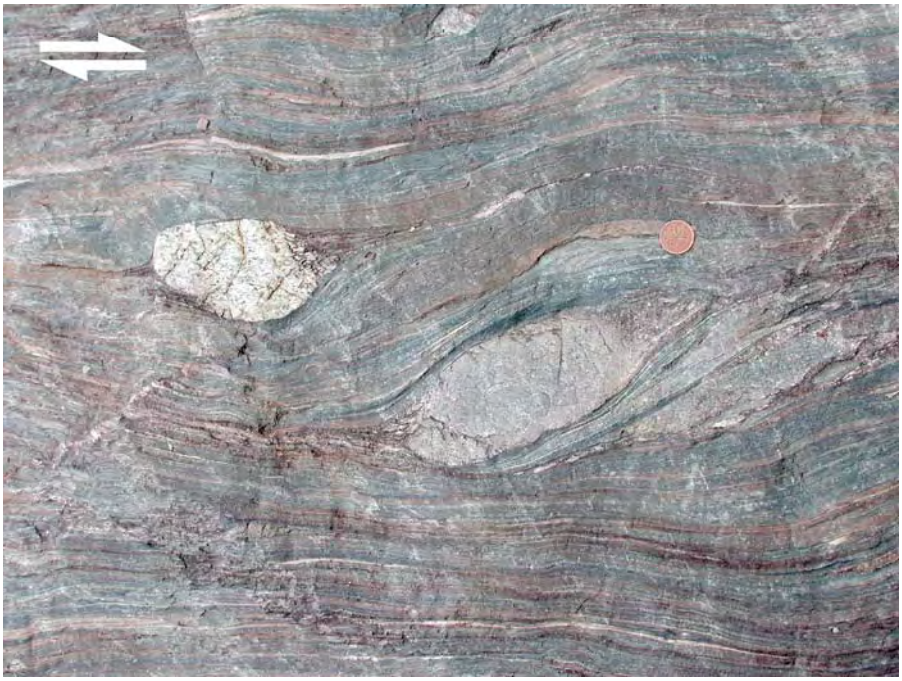

Photo 8. Asymmetric pressure shadows on pebbles in highly strained Timiskaming conglomerates. Plane of view is approximately parallel to stretching lineation L2, north is on the top. Oblique (counterclockwise) alignment of pressure shadows with respect to S2 foliation indicates dextral movement in the direction of stretching lineation, i.e., reverse (south side up)-dextral movement on the Larder Lake deformation zone.

GOLD MINERALIZATION

The accompanying geological map (Map P.3546–Revised, back pocket) shows the location of major gold occurrences. The most important occurrences of gold mineralization are the past-producing Upper Canada Mine and mineralized zones of the McBean and Anoki properties. Recent (1996-present) exploration campaigns of Queenston Mining Inc. and their joint venture partners resulted in the discovery of new significant gold mineralization in the McBean and Anoki areas. All known economic and potentially economic occurrences of gold mineralization are spatially associated with major high-strain zones. Mineralized zones of the McBean Mine and Anoki property (Anoki Main, Anoki South, Anoki Deep, and 40 East) occur within or in close proximity to the Larder Lake–Cadillac deformation zone; mineralization of the Upper Canada Mine is hosted by the Upper Canada deformation zone.

The following section describes the geology of gold occurrences focusing on structural geology and mineralization styles. At present, mineralization can be observed at surface only at the Upper Canada Mine, where the westernmost portion of the most productive L zone is exposed by strippings west of former shaft #2. Mineralization at Anoki and McBean is not exposed and was observed in drill core.

Upper Canada Mine

The Upper Canada Mine operated from 1938 to 1971 and produced 43.49 tonnes of gold at a grade of 10.3 g/t (information of Ontario Ministry of Northern Development and Mines, posted at http://www.mndm.gov.on.ca, downloaded in spring, 2005). Remaining measured and indicated resources are 13.11 t Au at an average grade of 6.9 g/t (Queenston Mining Inc. 2003). The history and general geology of the mine is described by Tully (1963). Most of the ore (66.8% as of 1961) was mined from the L mineralized zone, which is subdivided into the Upper and Lower L zones (Tully 1963). The roughly 600 m long Upper L zone extends from the surface to 575 m depth (the 1750-foot level), whereas the 300-350 m long Lower L zone was developed from 575 m (the 1750-foot level) to 2015 m (the 6150-foot level), the lowest level in the mine. Within the L zone, typical ore bodies are 30 to 60 m long (maximum about 170 m) and are separated by barren or weakly mineralized rocks (Bragg 1967). Other mineralized zones include the B, H, M, Q, and minor C and K zones (Tully 1963). Mineralization is hosted by strongly foliated Timiskaming volcanic rocks and related intrusions within the Upper Canada deformation zone ("Upper Canada Break", Tully 1963). All major mineralized zones strike parallel to the host deformation zone (i.e., east-northeast approximately 075º), dip steeply to vertically, and plunge 40º-60º east. As can be seen on the longitudinal section (Figure 10), the bulk of the ore occurs between the east-plunging stock of leucocratic syenite porphyry ("white spotted porphyry", Tully 1963) (west), and the contact of Timiskaming volcanics and turbidites (east). No ore has been found in turbidites and only the Upper L zone is partially hosted by the leucocratic syenite porphyry (Bragg 1967). Mineralization occurs as silicified zones accompanied by sericite-carbonate alteration; fine native gold is associated with pyrite and less abundant chalcopyrite, arsenopyrite, tennantite-tetrahedrite, galena, altaite, molybdenite and scheelite (Tully 1963). Gold:silver ratio is 2.22:1 (Tully 1963). A series of northeast-trending discrete faults ("mud seams") cut deformed rocks in proximity to the gold mineralization (Tully 1963); these faults are most likely related to late, brittle, overprint of the ductile Upper Canada deformation zone. West of the mine, a post-mineralization diabase dike is dextrally displaced for about 110 m (345 feet) along the "main mud seam" (Tully 1963).

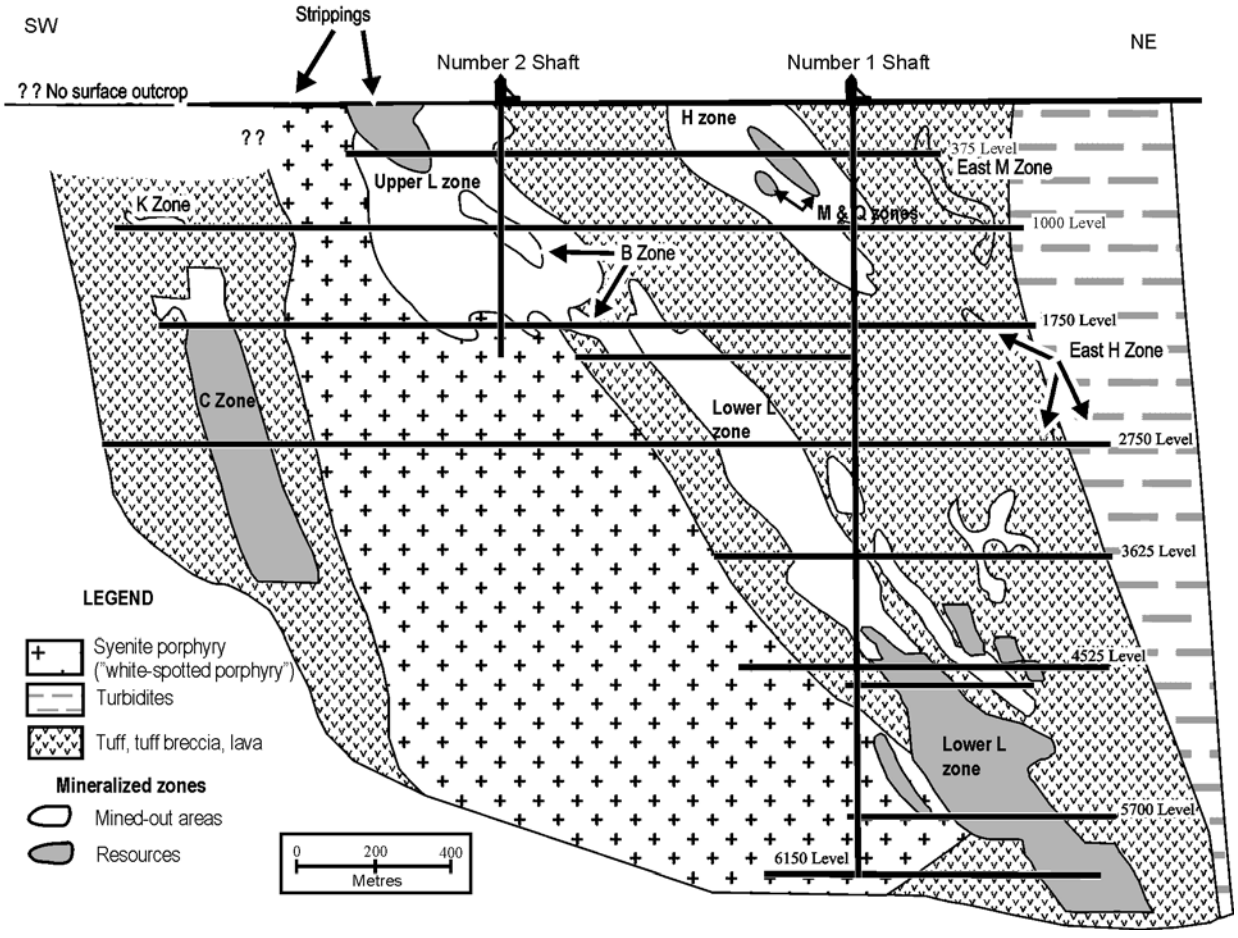

Figure 10. Longitudinal section of the Upper Canada Mine, with approximate position of stripped outcrops. Modified from a section posted at Queenston Mining Inc. website, www.queenston.ca and Stevenson et al. (1995).

The westernmost part of the L zone is exposed in stripped outcrops west of the former shaft #2 (Figure 11). Toogood (1989) mapped hydrothermal alteration assemblages and identified 3 generations of penetrative deformational fabrics. He attributed fabrics to dextral strike-slip shear along the Upper Canada deformation zone and concluded that gold mineralization postdated the first deformational fabric and was structurally and hydrothermally overprinted during the formation of the latest fabric. As part of the present project, we mapped the main "L" stripping at a 1:200 scale, and made additional structural observations on other stripped outcrops. Our study confirms several conclusions of Toogood (1989), however there are also important differences. The following sections on the geology of the Upper Canada Mine are based primarily on our new mapping and structural observations. A geologic map of the L stripping is presented in Figure 12 (back pocket). Outlines of stripped outcrops on Figure 12, and gold grade information are from Toogood (1989). Geochemical data for 12 samples from the Upper Canada Mine area are presented in Appendix A; the location of samples from the "L" stripping is shown in Figure 12. Samples were intended primarily for microstructural studies and may not be representative of the gold grades established by the original channel sampling (Toogood 1989).

ROCK TYPES

The rocks exposed in stripped outcrops (Figure 11) include tuff, tuff breccia, and leucocratic feldspar-phyric syenite porphyry ("white spotted porphyry" of Tully 1963). Tuffs are generally strongly altered and consist largely of hydrothermal sericite, fine-grained quartz and carbonate. At the L-NW stripping, (Figure 11), where quartz-sericite-carbonate alteration is weaker then elsewhere, the tuffs contain abundant secondary chlorite. Most tuffs are aphanitic and do not contain identifiable crystals or rock clasts. However, at a few places at the L stripping, sparse (<5-10%) relict feldspar grains (0.5-2 mm) can be seen in tuffs. Tuff breccia consisting of angular (1-5 cm to 7-10 cm) lithic clasts enclosed in a strongly tourmalinized matrix comprises a distinct rock type exposed on the L and L4 strippings.

Leucocratic feldspar-phyric syenite porphyry contains 20-40% ovoid feldspar phenocrysts set in an altered (quartz-sericite ± carbonate) matrix. These rocks form a wedge-like, eastward-tapering body parallel to the general trend of the Upper Canada deformation zone. Between the L-W and L-NW strippings, the width of the intrusion is about 70 m, near the eastern end of the L stripping, the body is only about 5 m wide. The exposed westernmost portion of the L mineralized zone is spatially associated with the narrow "nose" of the syenite body (Figure 11). As can be judged from the block-diagram in Tully (1963) and the longitudinal section of the mine (Figure 10), the wedge-shaped syenite body tends to widen with depth and the line of its eastern termination plunges about 40-50º east. Association of the L zone with the eastern terminus of the intrusion generally persists with depth: the Upper L zone occurs at the contact and is partially hosted by the intrusion and the Lower L zone is located up to roughly 150 m east of the syenite body. In addition to widespread syenite porphyry, there are also pink, reddish-grey or grey fine-grained aphyric rocks that occur as lenses and discontinuous bands (e.g., 0.1 by 1 m to 1 by 4 m). Like all other rock types, these rocks are variably foliated and folded. Most probably, these rocks represent boudinaged small dikes (Toogood 1989) and they are shown as "aphanitic microdikes" on Figure 12.

The L stripping (Figure 12, back pocket) exposes the westernmost part (roughly 70 m) of the L mineralized zone. The main rock type is the leucocratic syenite porphyry, bounded by tuffs and tuff breccias, to the north and south, respectively. The nature of the northern contact of the intrusion varies in the outcrop. West of the channel sampling line 11 where syenite porphyry is bounded by aphanitic tuffs, the contact is sharp and quite distinct in the outcrop, whereas east of this channel sampling line, the contact is more diffuse. The syenite porphyry still has a distinctive porphyritic texture defined by the presence of 30-35% feldspar phenocrysts, but strongly altered and foliated rocks north of the inferred porphyry contact also contain sparse (typically ≤ 5%) relic feldspar grains. Although these feldspar-bearing rocks are interpreted as tuffs, they could represent strongly altered and sheared syenites.

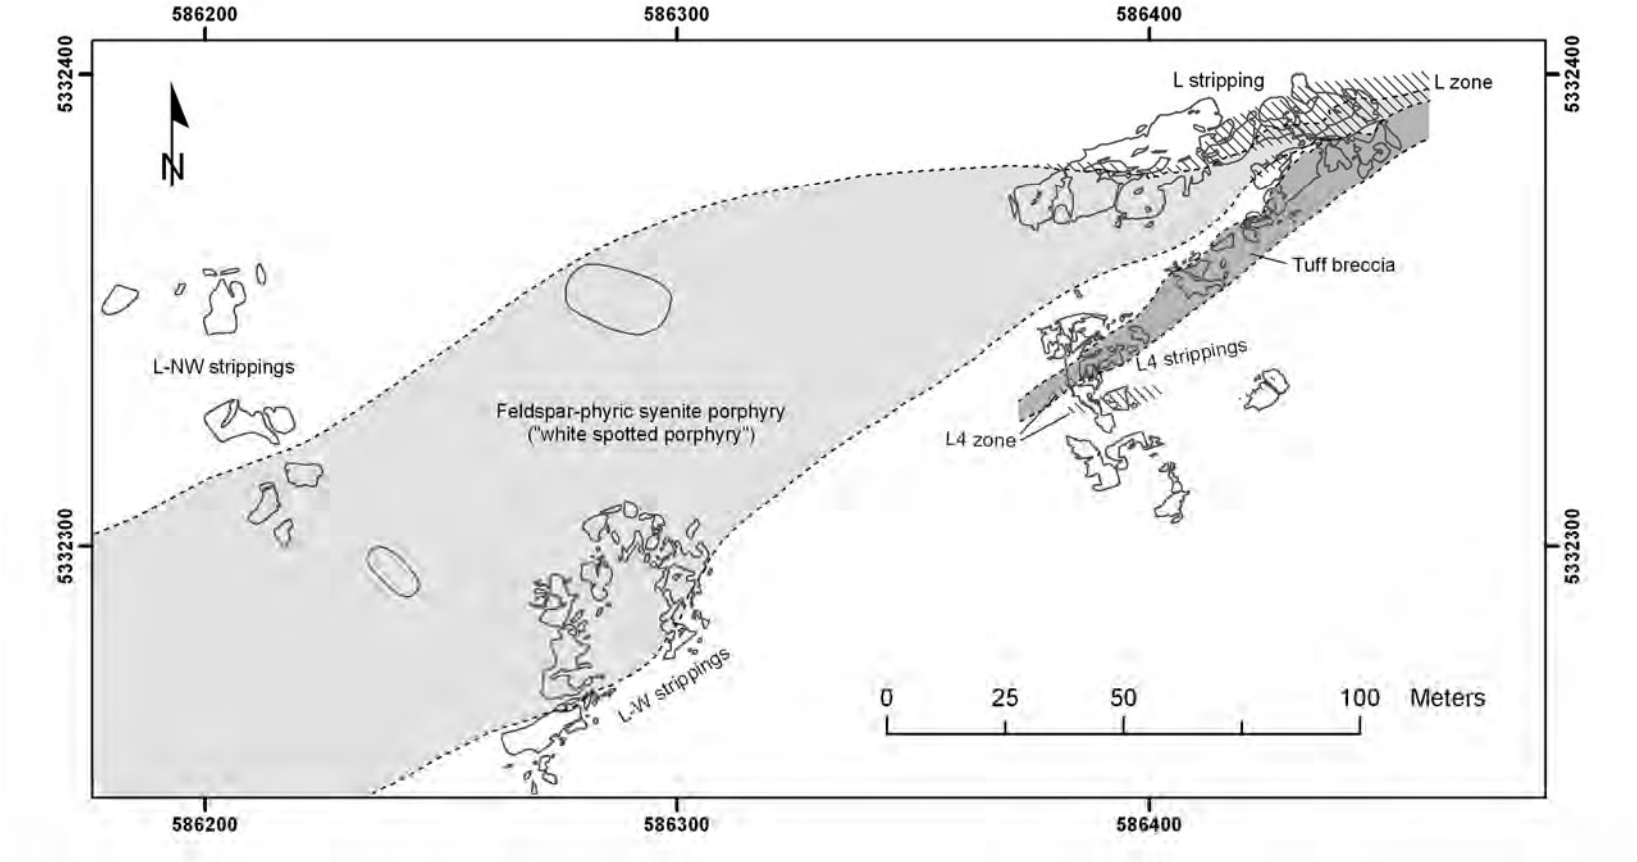

Figure 11. Location of stripped outcrops west of former Upper Canada shaft #2, inferred contacts of the leucocratic syenite porphyry ("white-spotted porphyry") intrusion, and location of mineralized zones. Outlines of stripped outcrops are from Toogood (1989).

HYDROTHERMAL ALTERATION

All rocks exposed in the stripped area are hydrothermally altered. There is a ubiquitous quartz-sericite-carbonate alteration characterized by variable carbonate abundance. Distinct carbonate-rich (CO_2 approximately 8-14%) schistose rocks occur along the north contact of the syenite porphyry body and are shown as quartz-sericite-carbonate schists on Figure 12. As discussed below, these carbonate-rich schists constitute the gold-bearing zone between channels 10 and 16. Toogood (1989) identified the carbonate as ankerite or ferroan dolomite based on staining tests. Finely disseminated pyrite is present in quartz-sericite-carbonate-altered rocks throughout the stripping, and the abundance of pyrite does not appear to be related to the intensity of carbonatization. Tourmalinization occurs locally, and tends to be spatially associated with a tuff breccia horizon exposed in the southeast part of the L stripping and on the L4 stripping. In addition to the tuff breccias, weak tourmalinization was also microscopically observed in the syenite porphyry (L stripping, channel 14). The 2-10 cm thick veins of translucent quartz (also containing albite and carbonate) are widespread and belong to two major groups: folded early veins parallel or near parallel to S2 foliation; and late, steep, north-south-trending veins crosscutting all deformational fabrics. Throughout the L stripping, most veins are barren, with the exception of the area of quartz veining sampled by channel 3.

STRUCTURAL GEOLOGY

Three penetrative deformational fabrics are observed in stripped outcrops. They correlate with the regional deformation fabrics described above. The earliest foliation, S2, is steeply dipping and northeast striking (065-085°, in places to 100°; Figures 12, 13, 14, 15, 16, and 17). In the tuffs, S2 is a differentiated foliation defined by domains rich in carbonate, quartz, and feldspar (?) alternating with thinner sericite-rich domains (Photo 9). S2 is also expressed by alignment of individual mica flakes, quartz ribbons, feldspar porphyroclasts in syenite porphyries, and by flattened lithic clasts in tuff breccia. In thin section, trains of fine pyrite and titanite also mark S2 foliation.

S2 is overprinted by a differentiated crenulation cleavage S3. On the L-W stripping, north portion of the L4 stripping, and a few locations on the L stripping, S3 is oriented approximately north-south (340º-020º), at a high angle to S2. On the L-W stripping, in altered syenite porphyry, north-striking S3 is marked by diffuse, 1-2 mm wide sericite-rich cleavage bands oriented at a high angle (60-70º counterclockwise to almost orthogonally) to S2, and axial planar to open folds of S2 (Figures 14 and 15, Photo 10). Under the microscope, sericitic cleavage bands are noted to contain fine pyrite and titanite(?).

In the north part of the L4 stripping, the diffuse S3 cleavage bands trend 330º-340º and are nearly orthogonal to S2. S3 is marked by rosettes and irregular clusters of hydrothermal tourmaline and very fine titanite (?) grains. Tourmaline also occurs along S2. Some euhedral tourmaline crystals are oriented at high angle to S3 planes, indicating that tourmalinization either postdated the formation of S3 or possibly occurred during its final phases. Both tourmaline-bearing fabrics are overprinted by northeast-trending (065º-070º) S4.

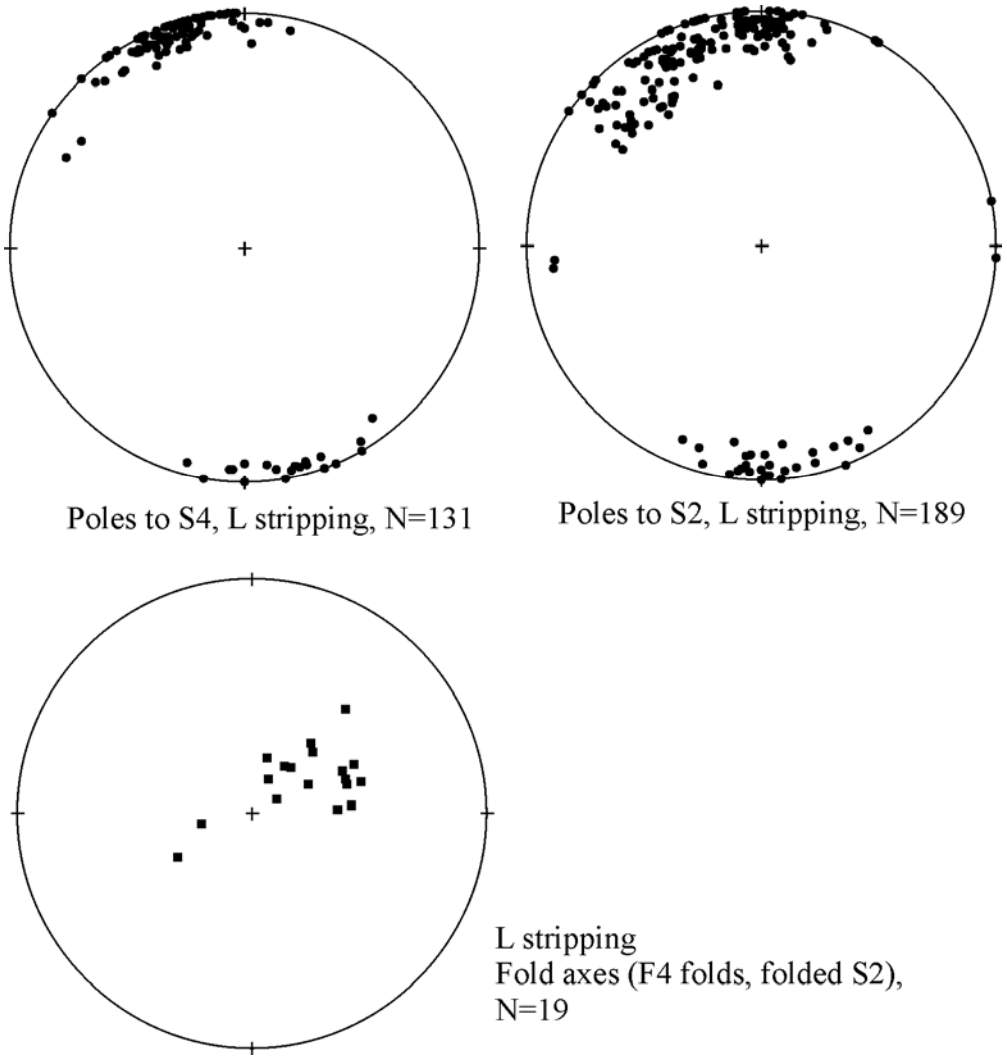

Figure 13. Steronet plots of S2, S4, and fold axes from the L stripped outcrop.

Photo 9. S2 in gold-bearing quartz-sericite-carbonate schists, defined by intercalating bands variably rich in silica, sericite, and carbonate. S2 is folded into Z-asymmetric folds (F4). Upper Canada Mine, L stripping, sampling line 13, looking south. Syenite porphyry (light tones) along the upper margin of the photo.

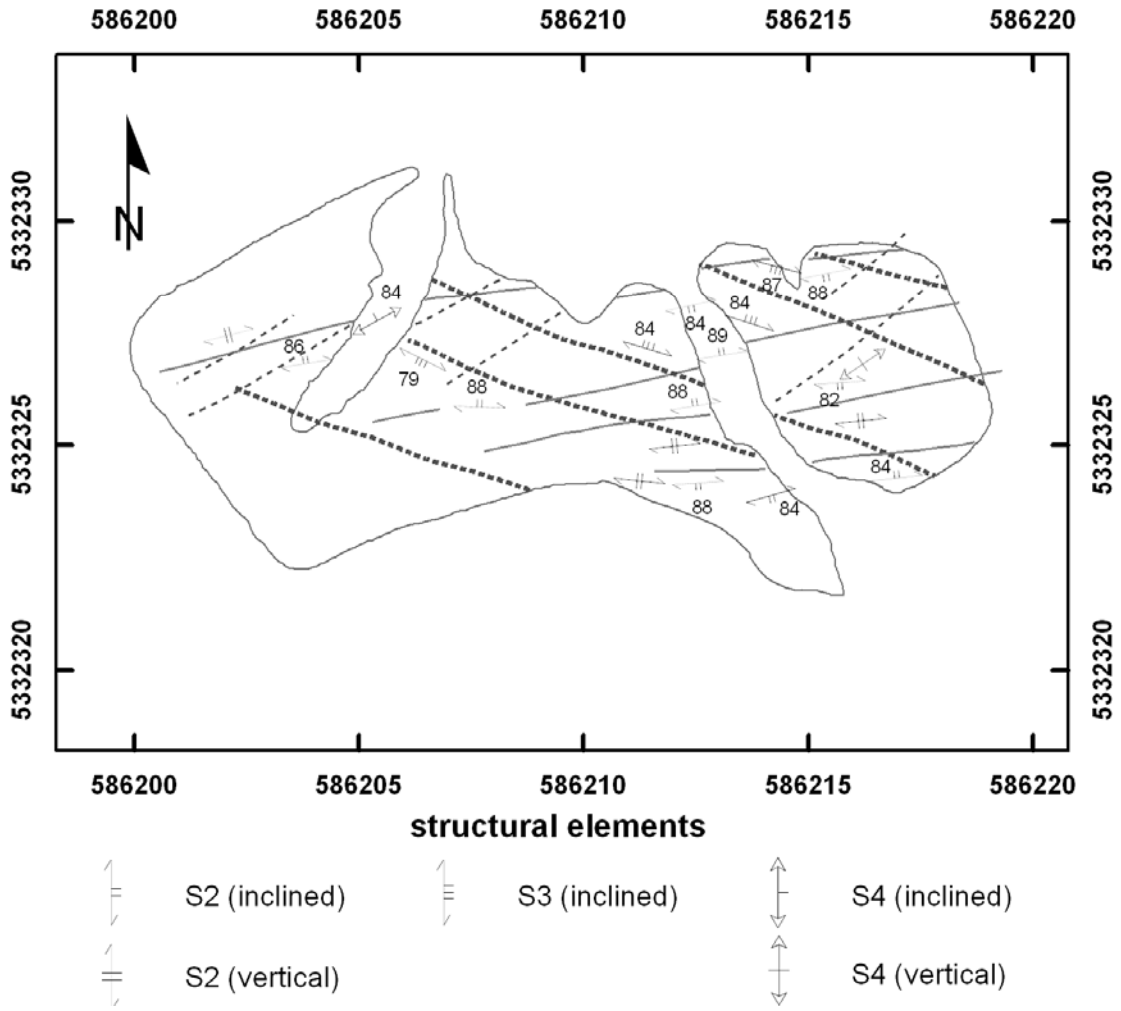

Figure 16. Fragment of the L-NW stripped outcrop: relationships of S2, S3, and S4. Solid lines-S2; thick dashed lines-S3; thin dashed lines-S4. Outcrop outlines are from Toogood (1989).

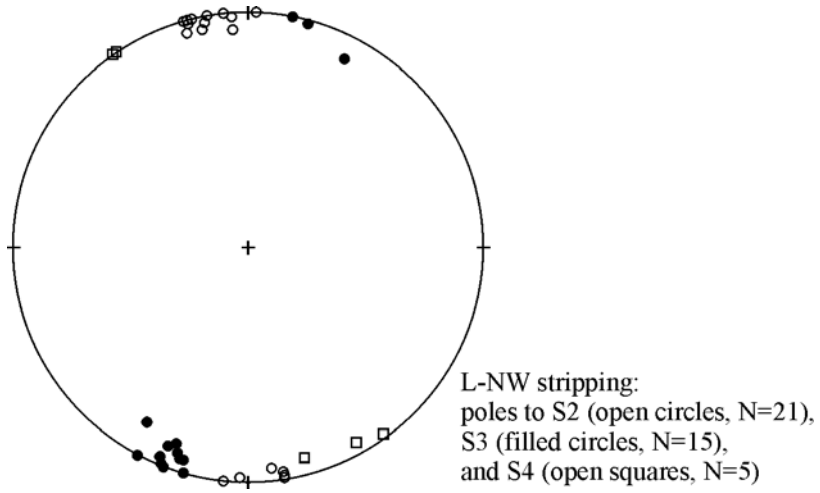

Figure 17. Stereonet plot of S2, S3, and S4 on the L-NW stripped outcrop (area shown on Figure 16).

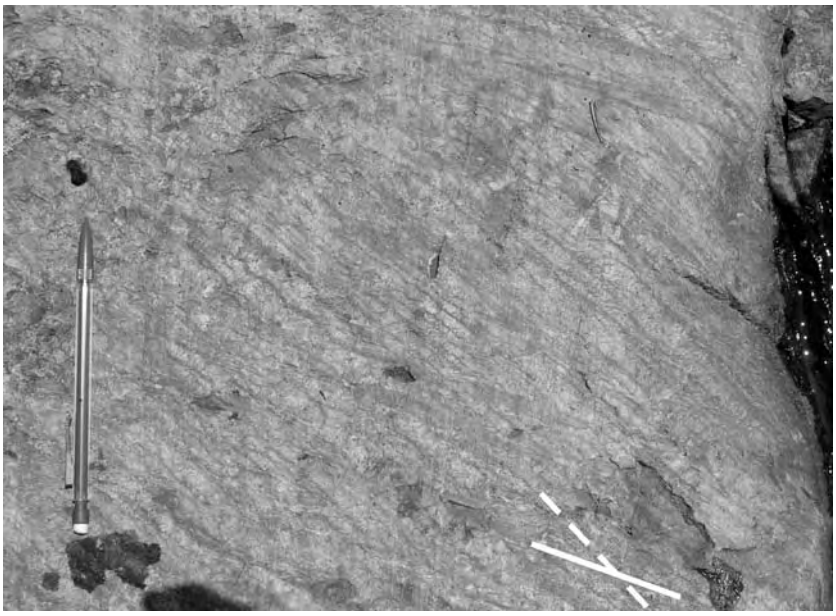

Photo 11. S3 (dashed line) oriented clockwise to S2 (solid line). Upper Canada Mine, L-NW stripping. Pencil is 15 cm.

Photo 12. Closer view of S3 defined by dark 1-2 mm wide chlorite-rich cleavage bands separating quartz-carbonate-rich microlithons. Upper Canada Mine, L-NW stripping. Diameter of the coin is 2 cm.

At the L-NW stripped outcrop (Figures 16 and 17, Photos 11 and 12), there is a drastic change in the orientation of S3. S3, defined by 0.5-2 mm wide chlorite-sericite-rich bands, trends southeast (100º-110º) and is oriented approximately 30º clockwise to S2. In quartz-carbonate-rich microlithons, S2 typically shows S-asymmetric crenulation, indicative of dextral slip parallel to S3. In thin section, some sharp S3

planes are marked by trains of very fine-grained brown, near opaque leucoxene (?), probably representing insoluble residue left by pressure solution. Some discrete cleavage planes are noted to offset S2-parallel silica-rich bands, without preserving continuity of the latter.

Both S2 and S3 are overprinted by a steeply dipping, northeast-trending (065-080º), S4 foliation (Photos 13, 14, and 15). At the L-NW stripping, S4 occurs as thin discrete crenulation cleavage of S2 and S3. At the L-W stripping, tightly spaced S4 defines a shear zone in which tightly folded S3 underwent dextral (clockwise) rotation. On the L stripping, the overprint of S2 and S3 by S4 is particularly strong. North of the quartz-sericite-carbonate schist, S2 is isoclinally folded and transposed parallel to S4 with locally preserved intrafolial detached fold hinges. Originally north-trending S3 is also partially or completely transposed parallel to S4. Rotation of S3 into parallelism with S4 does not follow a consistent pattern: cases of both clockwise and counterclockwise rotation are documented on the L stripping. In thin sections from the L stripping, S4 is defined by discrete sericite- and pyrite-rich cleavage planes, transposed S2 and probably S3, and quartz fibres in fringes around pyrite grains. Pyrite trains along S4 planes locally transect pyrite-poor siliceous layers in microfold hinges, which supports at least some hydrothermal re-distribution of pyrite. In thin sections from the L-NW stripping, S4 occurs as a sharp discrete crenulation cleavage that is usually better developed in mica-rich domains and is marked by very fine opaque grains, possibly leucoxene.

Photo 13. S4 (oriented roughly east west) overprinting S3 (north-south orientation) on the L stripping. Plan view; south is at the top of the photo. Coin diameter is 1.8 cm.

Photo 14. Close-up view of the area shown on Photo 13. S2 (double line) is preserved in S3 microlithons (oriented parallel to the dashed line). S4 (solid line) is axial planar to microfolds of S3.

Photo 15. S4 (approximately east-west-oriented dark bands parallel to the white solid line, above the coin) axial planar to open folds of S3 (dashed line). Coin diameter is 2.4 cm. Upper Canada Mine, L stripping.

Within the band of quartz-sericite-carbonate schist, between channels 10 and 13, S2 is folded into northeast-plunging Z-asymmetrical folds with locally developed steep axial planar cleavage striking 030º-045º (Photo 9). In the syenite porphyry immediately south of this schist, Z-asymmetrical to symmetrical folds plunge 60-70º (to almost vertically) northeast and have steep, northeast-striking (about 030º-040º) axial planar cleavage (Figure 12). These folds are interpreted as F4 folds. Their axial planes are oriented counterclockwise with respect to S4 in highly strained tuffs (north of the syenite porphyry), possibly reflecting clockwise rotation of folds during the shear. Although the Z-asymmetry of F4 folds is more typical, it is important to note that east-northeast-plunging symmetrical and S-asymmetrical folds of S2 with axial planar S4 occur in the eastern part of the L stripping.

In addition to the pervasive fabrics described above, a non-pervasive crenulation foliation striking 110-120º is locally observed on the stripped outcrops. It postdates S3 and is overprinted by S4. At present, the significance of this fabric is not clear.

GOLD MINERALIZATION

Information on gold grades for the L stripped outcrop compiled from Toogood (1989) is shown in Figure 12. No quantitative assay data are available; gold grades are illustrated by bar graphs depicting variation from 1 to 10 g/t. The graphs do not differentiate the grades above 10 g/t; however, as evident from the original report, some values exceeded this arbitrary limit, reaching up to 28 and 42 g/t (Toogood 1989).

Toogood (1989) noticed a difference in gold grade distribution west and east of channel sampling line 11. West of this channel, gold occurs within a 0.3-2.0 m wide sharply bounded band of the quartz-sericite-carbonate schist at the north contact of the syenite porphyry body. Gold grades $\geq$ 10 g/t are fairly common in these carbonate-rich rocks. East of channel 11, the mineralized zone becomes wider. Grades $\geq$ 1 g/t occur over an 8-10 m wide zone, mostly north of the syenite porphyry body, and limits of mineralization, especially its north boundary, are no longer sharply defined. (A band of the quartz-sericite-carbonate schist can be traced to channel 7; it constitutes the southern flank of the mineralized zone between channels 7 and 10.) The swell of the mineralized zone is accompanied by a decrease in the average gold grade (Figure 12; see also Toogood 1989).

The mineralized zone trends 095º west of channel 13, and 070º east of it. Practically over its entire exposed length, mineralization occurs in pervasively quartz-sericite-carbonate-altered rocks with disseminated fine-grained pyrite. Most typical is a banded to laminated texture defined by intercalated S2-parallel carbonate-, sericite- and silica-rich, 2-5 mm wide bands (Photos 9 and 16). Some of these thin carbonate- and quartz-rich lamellae may be classified as veinlets, but due to their pervasive nature and impossibility to outline discrete veinlet swarms or vein zones, it is more appropriate to consider them as part of the pervasive alteration.

Apart from the quartz-sericite-carbonate schist, it is difficult if not impossible to distinguish gold-bearing from barren rocks in the outcrop. For example, between channels 8 and 11, tuffs exposed north of the assay-defined mineralized zone are strongly sericitized and silicified and contain abundant disseminated pyrite, but their gold grades are less than 1 g/t.

In one locality (channel 3), high gold grades correspond to an area of extensive quartz veining. These veins are macroscopically similar to barren veins seen elsewhere in outcrop. They may be more carbonate- and pyrite-rich (Toogood 1989) but the strong oxidation masks their original mineralogy. The material that was sampled by channel 3 included both veins and host rocks, and high grades may be related to gold contained in mineralized host rocks. Alternatively, the quartz veins in this part of the L zone may be gold bearing and different from barren veins observed in other parts of the outcrop.

Photo 16. Close-up view of L mineralized zone in quartz-sericite-carbonate-altered tuffs (L stripping, near sampling line 7). Distinct are pervasive quartz-carbonate bands and veinlets (0.3-1 cm thick) separated by darker, sericite-rich bands.

In cut slabs and thin sections of the gold-bearing carbonate-rich schists (channels 10, 11 and 12), mineralized rock consists of interlayered 1-3 mm wide sericite-, carbonate- and silica-rich bands. This compositional banding defines the S2 foliation in altered rocks, along with alignment of individual mica flakes and strained quartz ribbons. Fine-grained (0.1-0.2 mm), largely anhedral pyrite occurs predominantly in sericite-rich layers, sometimes additionally concentrating along their boundaries. Native gold was observed in cut slabs and thin sections collected near channel 11 (sample 11-1, Figure 12, Photos 17 to 20). Gold (0.02-0.1 mm to 0.5 mm) occurs in thin (1-3 mm), carbonate-rich (carbonate>quartz), quartz-carbonate bands or veinlets that are parallel to S2 foliation and are folded with axial planar S4 (Photos 17 and 18). Gold shows no preferential association with S2-S4 –parallel pyrite segregations: gold grains are typically enclosed in quartz-carbonate gangue outside foliation-controlled pyrite clusters (Photos 18 and 19). Tennantite ($(Cu,Fe)_{12}As_4S_{13}$, identification confirmed by SEM) and minor chalcopyrite are associated with gold (Photos 19 and 20). In one location, a cluster of gold grains is accompanied by a few pyrite grains, some of which enclose small gold particles. Scheelite and relatively rare euhedral rhombic arsenopyrite are present in some gold-bearing quartz-carbonate bands or veinlets. Scanning electron microscope imaging of anhedral pyrite grains clustering along S2 foliation planes revealed no detectable gold inclusions in pyrite. Gold-bearing quartz-carbonate bands and veinlets appear less strained than some silica-rich bands defining S2. This may indicate that the veinlets were emplaced relatively late in the D2 deformation.

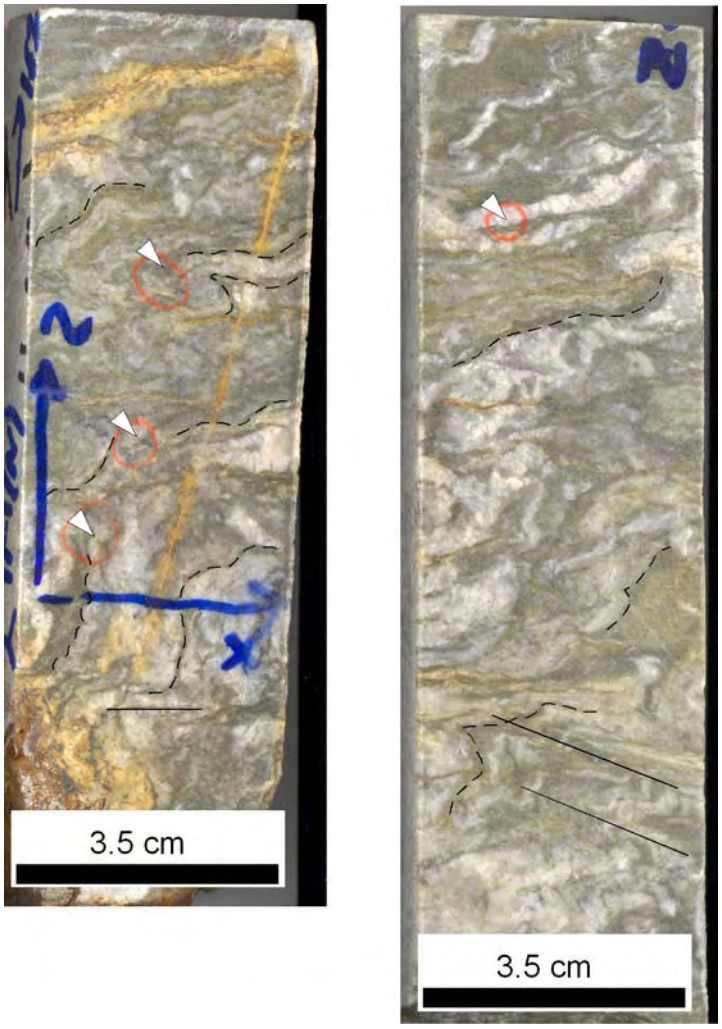

Photo 17. Cut samples from the Upper Canada L mineralized zone (gold-bearing quartz-sericite-carbonate schist near sampling line 11). The rock consists of intercalated sericite (dark)-, silica-, and carbonate (light)-rich bands that define S2. S2 (dashed lines) is folded with locally visible axial planar S4 (solid lines). Note that photographed surfaces are overturned from their actual orientation (as if they were viewed from inside outcrop upwards), as a result, folds show opposite (mirrored) asymmetry. In "normal" plan view, the folds are Z-asymmetric (see Photo 9 for the general outcrop view). Macroscopically visible (0.5-1 mm) native gold occurs in folded, S2-parallel, thin (2-5 mm) quartz-carbonate bands and veinlets (white pointers mark gold grain locations). Folding and S4 postdate gold mineralization.

Photo 18. Photomicrograph (plane polarized light) of folded carbonate-rich gold-bearing veinlet transected by S4 cleavage plane ("vertical" train of opaque grains (pyrite) along the right-hand margin of the photo). Field of view is 4 mm. Rectangle corresponds to the area shown on Photo 19.

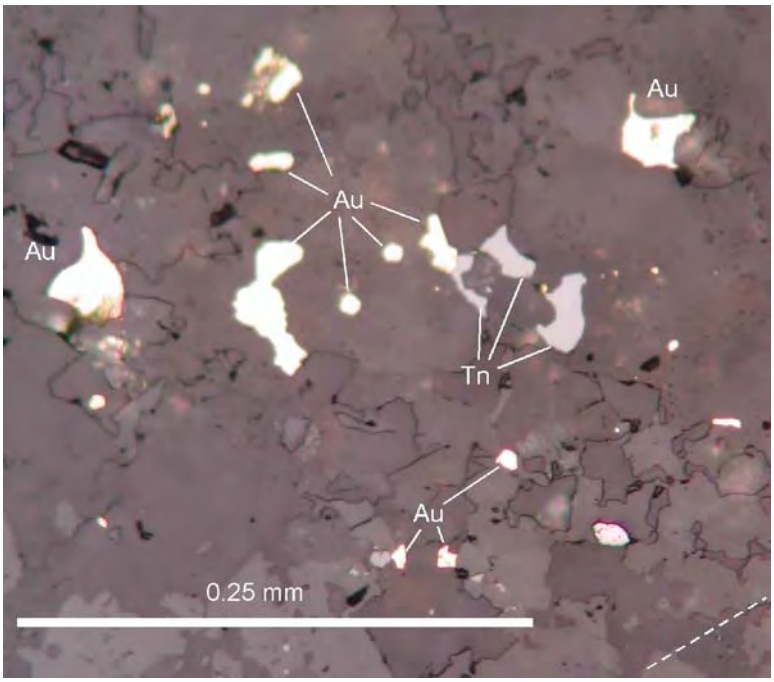

Photo 19. Reflected light photomicrograph of the rectangular area from Photo 18: Au, native gold; Tn, tennantite.

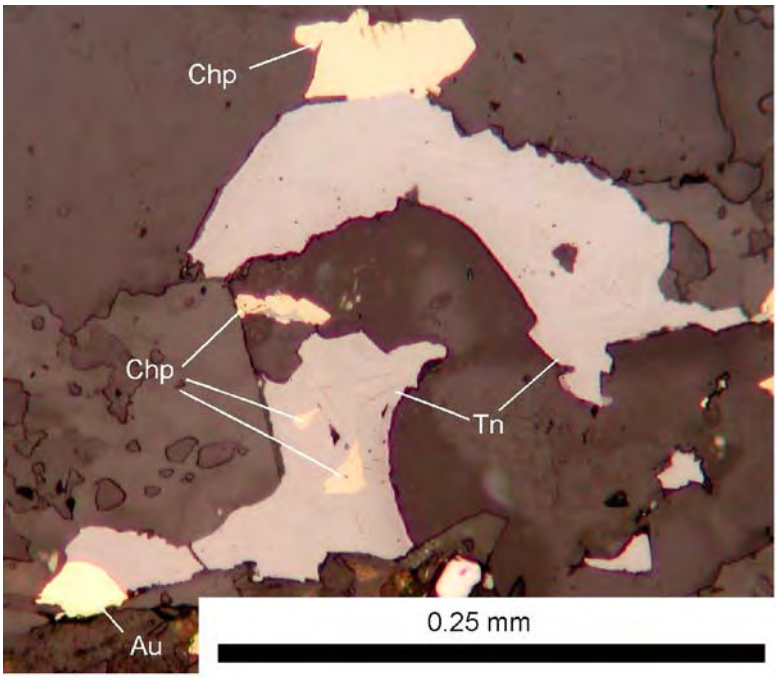

Photo 20. Reflected light photomicrograph: intergrowth of native gold (Au) with tennantite (Tn), and chalcopyrite (Chp) (Upper Canada Mine, L stripping).

RELATIVE TIMING OF DEFORMATION, HYDROTHERMAL ALTERATION AND GOLD MINERALIZATION

Relationships of alteration mineral assemblages and deformation fabrics documented in outcrops and thin sections suggest that there are multiple generations of quartz, sericite, and carbonate. However, the most extensive quartz-sericite-carbonate alteration broadly overlapped with the formation of S2, and possibly partially predated it. All subsequent stages of deformation were imposed on strongly sericitized, silicified and variably carbonatized rocks. This is because S2 is a compositional foliation defined by bands of deformed hydrothermal mineral aggregates. Formation of S2-parallel auriferous quartz-carbonate veinlets and extensive carbonatization within the gold-bearing zone is part of the main syn-D2 alteration event. The fact that gold-bearing quartz-carbonate (carbonate-rich) veinlets are more weakly strained compared to some silica-rich bands suggests that these veinlets could have formed relatively late in the D2 event. Some subordinate carbonatization occurred afterwards (probably episodically throughout the deformation history) as suggested by the presence of euhedral carbonate rhombs, scattered or clustering in small patches and overgrowing S2, S3, and S4. Similarly, apart from S2, sericitization is also associated with S3 (e.g., L-W stripping) and S4. The occurrence of S4-parallel quartz fibres in fringes around pyrite grains indicates at least some deposition (or redistribution) of silica during the latest deformation phase. In addition to these late quartz occurrences, there are barren quartz-carbonate veins that cut across S4. Pyrite is associated with S2; it also occurs along S3 foliation planes (e.g., L-W stripping), and is quite abundant along S4. Pyrite along S4 planes could have partially resulted from transposition of S2-related pyritic bands, and possibly accumulated as an insoluble phase during pressure solution along S4. However, some hydrothermal re-deposition probably took place. The typical anhedral shape of most pyrite grains may reflect their early deposition and subsequent deformation and partial dissolution. Unlike carbonate, sericite, quartz and pyrite, hydrothermal tourmaline was emplaced in a single late event. Relationships of tourmaline and deformational fabrics suggest that tourmalinization occurred after (or was partially

synchronous with) S3 and pre-dated S4. Tourmalinization does not appear to bear any significance for gold mineralization at the Upper Canada Mine.

The 0.02-0.1 mm grains of native gold occur in S2-parallel, quartz-carbonate bands or veinlets and are not associated with abundant anhedral pyrite clustering along S2 and S4 planes. The presence of some submicroscopic gold in pyrite is possible, but this gold is unlikely to contribute significantly to the overall grade balance. Although available geochemical data are insufficient for robust statistical analysis, there is no tendency for correlation between gold grades and sulphide abundance expressed as sulphur percentage. Occurrence of gold in carbonate-rich veinlets concurs with the overall nature of the mineralized zone, especially west of channel 11, where gold grades $\geq$ 1 g/t are confined to a sharply bounded band of particularly carbonate-rich (CO_2 approximately 8-13%) schists. S4 foliation and related folding overprint the mineralized zone as a whole and individual 1-3 mm thick gold-bearing bands and veinlets, as observed on outcrop- and thin-section scales. In summary, the Upper Canada mineralized system experienced protracted (episodic or continouus) hydrothermal activity that spanned 3 deformation events. Gold was introduced during a syn-D2 hydrothermal episode as replacement-style and sheeted veinlets, probably simultaneously with major carbonatization, and all subsequent deformation and alteration stages modified existing mineralization.

The effects of overprinting hydrothermal and deformational events on gold distribution are somewhat difficult to evaluate. Toogood (1989) proposed that larger width and lower gold grade in the eastern part of the L stripping is due to remobilization during the development of the S4. He also suggested that the 40-60º easterly rake of near-linear ore zones is controlled by the intersection of S2 and S4.

We believe that the late deformation and hydrothermal event could have modified mineralization, but presently available data are insufficient to attribute variations in grade distribution to the D4 overprint. Observed grade patterns may, for example, reflect original lateral variation in mineralization style and be completely unrelated to the post-mineralization overprint. Similarly, the apparent parallelism of ore shoots and S2-S4 intersection does not automatically imply structural control imposed by post-mineralization, syn-D4 modification. The moderate easterly plunge of the ore shoots is parallel to L2 stretching lineation, and may represent the original, syn-mineralization geometry.

KINEMATICS OF THE UPPER CANADA DEFORMATION ZONE

No unequivocal syn-D2 asymmetric shear-sense indicators were documented within the stripped part of the Upper Canada deformation zone. The near-vertical dip of the zone and lack of significant displacement of the geophysically distinct contact of turbidites and volcanic rocks east of the Upper Canada Mine suggests a strong component of flattening strain during D2. With respect to D4, conflicting kinematic indicators (e.g., both Z- and S-asymmetric folds, clockwise and counterclockwise rotation of S3 associated with S4 can similarly be interpreted as indicative of largely compressional strain during the late deformation stage.

Previously, Toogood (1989) interpreted the Upper Canada deformation zone as a dextral shear zone, with S2, S3, and S4 (S1, S2, and S4 in Toogood's original nomenclature) representing S, "ecc", and C fabrics, respectively (cf. Platt 1984; Berthe et al. 1979; Lister and Snoke 1984). We disagree with this interpretation for following reasons. S2 orientations range from about 060º to about 100º (Figures 13, 15, and 17), which cannot be considered as systematically counterclockwise to the estimated 070º strike of the deformation zone. The orientation of S3 on the L-NW stripping and predominantly S-asymmetric crenulation pattern match the expected geometry of extensional shear bands. However, as S3 is oriented at a high angle to S2 and is commonly axial planar to folded S2 (L-W stripping), it cannot be interpreted

as a dextral shear band fabric. S3 is a crenulation cleavage that overprints S2 and is in turn overprinted by S4, i.e., these fabrics are not contemporaneous. All 3 fabrics also occur outside the Upper Canada deformation zone, and are more probably related to consecutive regional deformation events rather than to the internal evolution of the Upper Canada deformation zone. Consequently, the geometric relationships between the three fabrics cannot be interpreted as shear sense indicators.

FACTORS CONTROLLING LOCALIZATION OF MINERALIZATION WITHIN THE UPPER CANADA DEFORMATION ZONE

Mineralized zones of the Upper Canada Mine occur within a roughly 1500 m long segment of the approximately 6000 m long Upper Canada deformation zone. The L mineralized zone that contributed 67% of gold production (Tully 1963) has a strike length of 300-600 m. On the scale of the deformation zone, gold-bearing rocks comprise an easterly plunging linear feature located close to the northeastern termination of the host structure. Factors controlling this location are not completely clear primarily due to the poor exposure of the area: almost the entire gold-bearing segment of the deformation zone east of former shaft #2 is unexposed. From what we presently know, two factors may potentially have played a role in localization of mineralization. The stock of rheologically more competent feldspar-phyric syenite porphyry ("white spotted porphyry") may have provided a "strain shadow" favourable for focusing fluid flow (e.g., Oliver et al. 2001 and references therein). Also, a northwest-striking turbidite contact discordant to the northeast-trending Upper Canada deformation zone may have acted as an impermeable barrier enhancing fluid focusing. Competency contrast between feldspar-rich syenite porphyry and less competent tuffs may have been a factor in small-scale localization of gold-bearing zones along the contact between the two rock types (e.g., L-stripping, Figure 12).

Gold Mineralization Along the Larder Lake–Cadillac Deformation Zone

ANOKI PROPERTY

Gold mineralization of the Anoki property comprises 4 major mineralized zones (Anoki Main, Anoki South, 40East, and Anoki Deep zones) and several smaller occurrences. All zones are outlined by drilling, and the Anoki Main zone is also developed by a ramp, which is presently flooded. Drill core from representative intersections of mineralized zones was examined as part of the present project. Geology of the Anoki property is shown on the accompanying geological map (P.3546–Revised, back pocket). A band of ultramafic talc-chlorite schists (Larder Lake Break, Thomson and Griffis 1941) separates mafic volcanic rocks of the Larder Lake Group (south) and Timiskaming sandstone-conglomerate sequence (north). Timiskaming alkalic volcanic rocks, expressed as a contrasting magnetic high on aerial magnetic maps, were uncovered by drilling 150-200 m farther north of the Larder Lake Group–Timiskaming contact. Compilation of drilling data of Queenston Mining Inc. revealed a pronounced flexure-like bend of the Timiskaming–Larder Lake Group contact in the western part of the Anoki area. There, the contact, marked by a band of talc-chlorite schists, changes orientation from about 110º to about 070º. The contact between Timiskaming volcanic and sedimentary rocks further north appears to follow the same pattern. Drilling also produced interesting data on deep structure of the south flank of the Larder Lake–Cadillac deformation zone (Figures 18 and 19). Basalts of the Larder Lake Group are underlain by a "South Splay" (Queenston Mining Inc. 2003), a northeast (roughly 070º)-striking and shallowly (35-40º) southeast-dipping fault marked by a sliver of variably carbonatized ultramafic rocks. Below this fault is a wedge-shaped unit of tuffs, sandstones and conglomerates that probably belong to the Timiskaming assemblage, although they are different from typical Timiskaming clastic rocks exposed and uncovered by drilling to the north. The South Splay is discordant to internal stratigraphy of the overlying Larder Lake basalt unit,

as seen from truncation of several interflow exhalite horizons, and of flow unit hosting the Anoki Main zone.

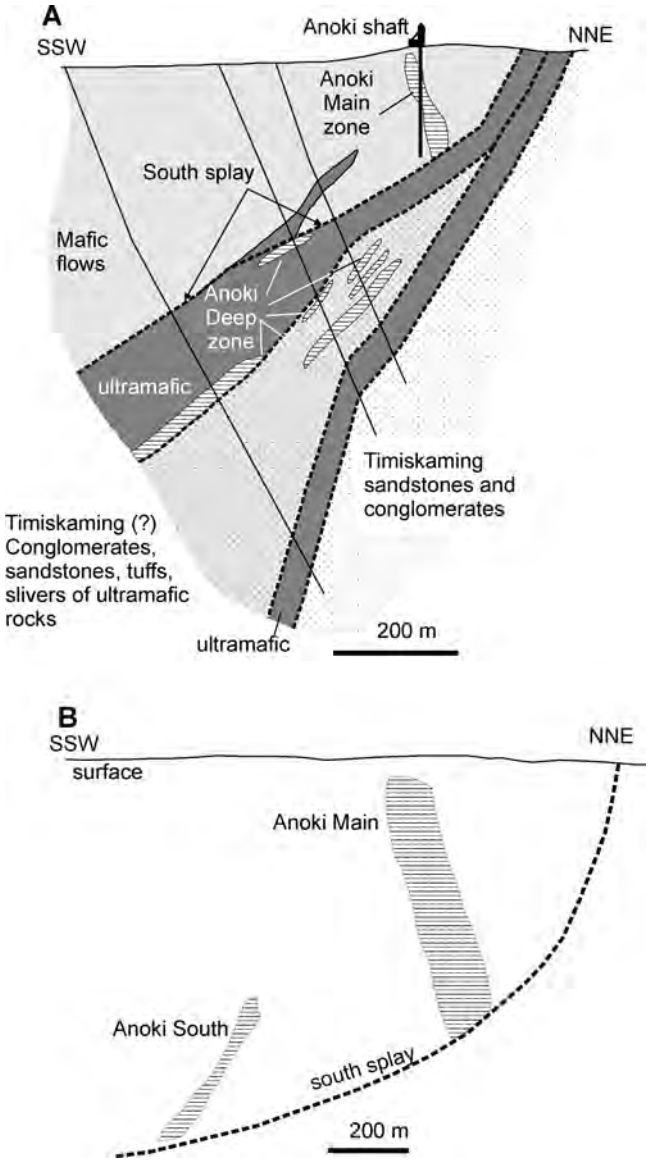

Figure 18. Deep structure of the south flank of the Larder Lake–Cadillac deformation zone in the Anoki area. A) schematic cross-section illustrating geologic setting of the "South Splay", Anoki Main and Anoki Deep mineralized zones (approximate location of the cross-section is shown in Figure 2). Modified from a cross-section posted at Queenston Mining Inc. website (www.queenston.ca), downloaded in spring 2005. B) schematic cross section (located approximately 350 m east of the cross section A), illustrating relationships of Anoki South and Anoki Main zone with the South Splay. Anoki South zone is spatially associated with an interflow exhalite horizon enclosed in mafic volcanic rocks. Modified from Queenston Mining Inc. (2003).

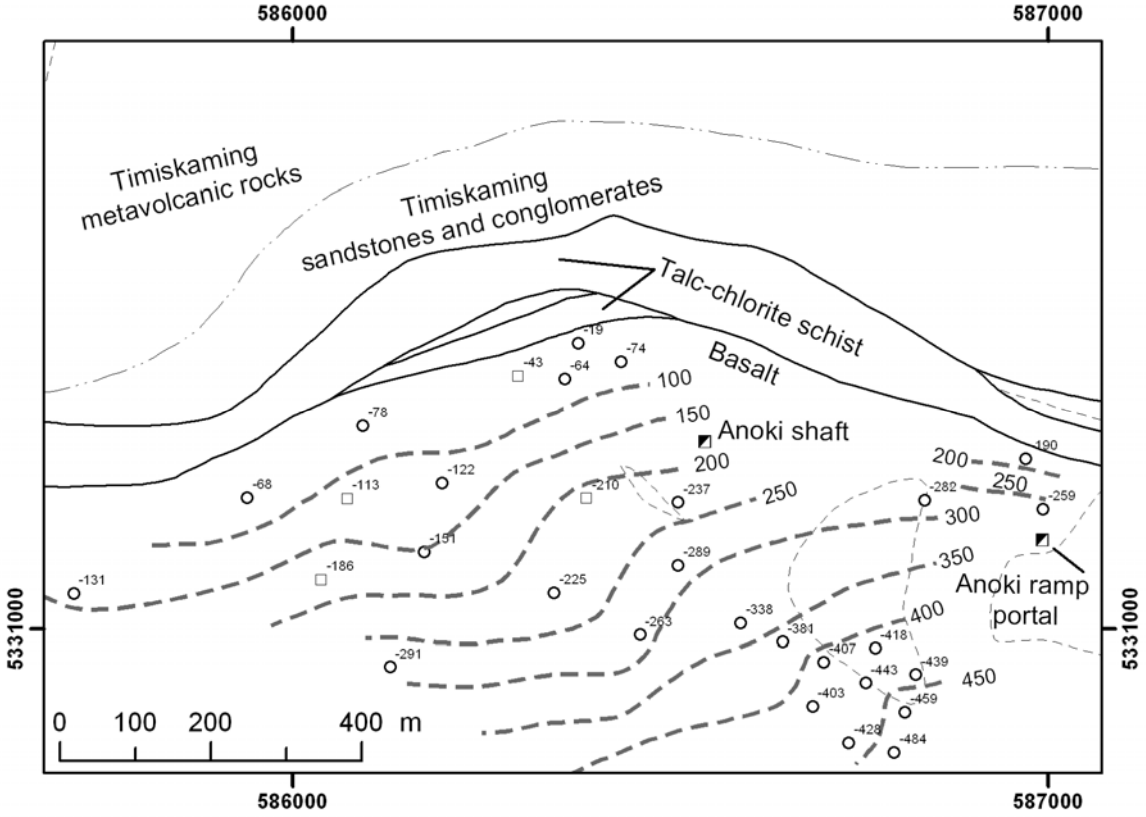

Figure 19. Contour lines (thick dashed lines, numbers depict depth from surface in m) of the lower contact of Larder Lake basalts corresponding to the "South splay" (Anoki area, see accompanying Map P.3546–Revised for general geology). Based on drilling data of Queenston Mining Inc. (squares and circles are drill intersections of the contact).

Anoki Main Zone

The Anoki Main zone is a steeply (approximately 60-65º) north-dipping, east-southeast-striking, mineralized zone hosted in basalts of the Larder Lake Group (Queenston Mining Inc. 2003). The accompanying map (P.3546–Revised, back pocket) depicts the location of the uppermost part of the zone ("Anoki" in the list of gold occurrences). In a longitudinal section view, the mineralized zone has a shape of a 60 by 450 m band, plunging about 30º to the east (Figure 20). The upper surface of the South Splay constitutes the lower limit of mineralization. The mineralized zone consists of seven lens-shaped bodies containing measured and indicated resources of 2.98 t Au with an average grade of 5.7 g/t and inferred resources of 0.2 t Au with an average grade of 5.7 g/t (Queenston Mining Inc. 2003). Mineralization is approximately concordant to the internal stratigraphy of the basaltic sequence: cross section in Figure 4 in Thomson and Griffis (1941) shows near-parallel orientation of the mineralized lens and interflow cherty exhalite beds. In the present study, Anoki Main zone mineralization was examined in drill core (holes AN96-01 and AN03-61, Queenston Mining Inc.). Mineralization is spatially confined to a compositionally and texturally distinct flow unit. The unaltered protolith is a greenish dark grey to very dark green, chlorite-rich, strongly magnetic rock, commonly containing coarse (1-2 mm) magnetite grains and, in places, feldspar phenocrysts and glomeroporphyritic segregations. Pillow-rim textures, fine

(hyaloclastitic ?) brecciation and inclusions of interflow cherts are recognized in places. Geochemical data for one relatively unaltered sample are presented in Appendix A (Table A.2); the major element signature of the rock, diagnostic of iron-rich tholeiite, was illustrated earlier (see Figure 4). Altered and mineralized rocks are massive, light grey to brownish light grey, and contain abundant pyrite cubes (1-3 mm, Photo 21). This is clearly a replacement mineralization; only few quartz and quartz-carbonate veinlets (0.3-1 cm thick) are present. Where bulk alteration is relatively weak, distinct 2-3 cm wide bleaching and sulphidation halos around thin quartz stringers are observed (Photo 22). In thin sections, mineralized rocks consist of massive aggregate of variably oriented euhedral to subhedral hydrothermal albite, carbonate, coarse (1-5 mm) pyrite, with minor quartz and relatively sparse sericite. Gold is macroscopically invisible and occurs as very small inclusions in pyrite. In thin section from a relatively high-grade interval (22 g/t), one gold particle 0.04 mm was observed in a fractured pyrite grain. Scanning electron microscopic (SEM) examination revealed the presence of sparse 2-10 μm rounded or veinlet-like gold segregations in pyrite (Photo 23). Perhaps a significant proportion of gold is present in even finer, disseminated or lattice-bound form, undetectable by SEM. Pyrite grains also contain inclusions of chalcopyrite (Photo 24), and more rare sphalerite and galena. In addition to 5-7% sulphur content related to strong pyritization, the Anoki Main zone is characterized by elevated Cu and As (Appendix A).

The sulphide-rich replacement mineralization, where micron-size gold is disseminated in pyrite, is most likely a result of sulphidation of an Fe-rich, high Fe/Mg protolith (e.g., Phillips et al. 1984; Ridley et al. 1996; Böhlke 1988). Similar depositional mechanisms are interpreted to have occurred at the Kerr Addison-Chesterville Mine hosted by the Larder Lake–Cadillac deformation zone (Smith et al. 1993; see also further discussion of Kerr Addison geology) and at the Holloway Mine spatially associated with the Destor–Porcupine deformation zone (Ropchan 2000; Ropchan et al. 2002). The Fe/Mg (weight %) ratio of the Anoki Main zone ranges from about 4.5 to about 7, which approximates or slightly exceeds corresponding ratios of Kerr Addison replacement "flow ore", and is generally below, but still comparable with the very high Fe/Mg values of the Holloway Mine mineralization (Figure 21). High Fe/Mg ratios favour formation of pyrite, whereas at low ratios (initial molar Fe/(Fe+Mg)<0.5) all Fe tends to be incorporated into Mg-rich carbonate, and sulphidation does not occur (Böhlke 1988). Molar Fe/(Fe+Mg) ratio of the Anoki Main zone protolith is approximately 0.65, i.e., the composition of the rock is favourable for sulphidation reactions.

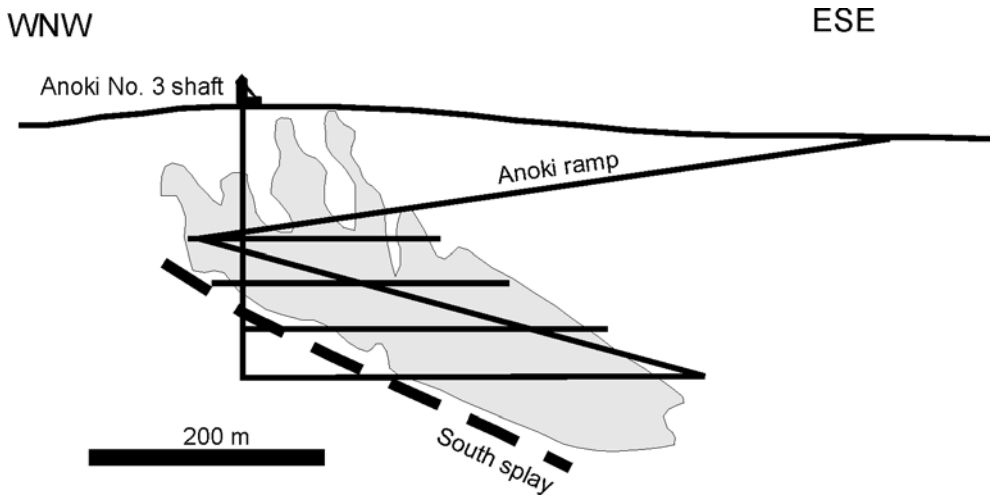

Figure 20. Anoki Main zone longitudinal section (modified from Queenston Mining Inc. 1996).

Photo 21. Strongly altered (albite, carbonate, pyrite, quartz) gold-bearing rock, western flanks of the Anoki Main zone.

Photo 22. Drill core from western flanks of the Anoki Main zone. Sulphidation (pyrite) halo around a thin (2-3 mm) quartz stringer.

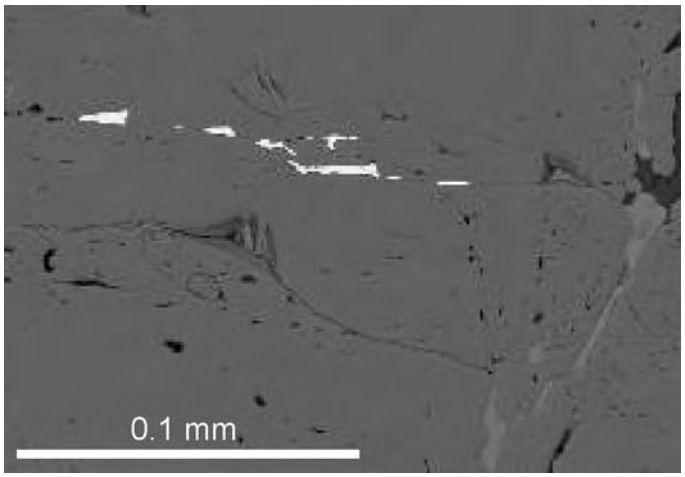

Photo 23. Backscattered electron image: veinlet-like segregation of gold (white) in pyrite (dark grey background) (Anoki Main zone).

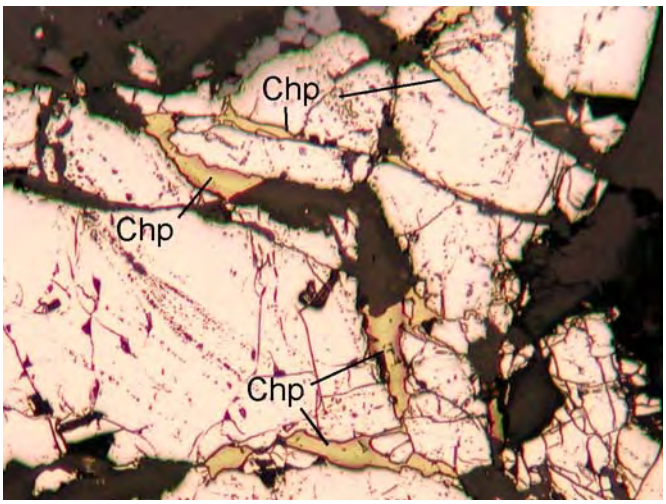

Photo 24. Photomicrograph (reflected light) of the Anoki Main zone mineralization: irregular segregations of chalcopyrite (Chp) in fractured pyrite (field of view is 0.25 mm wide).

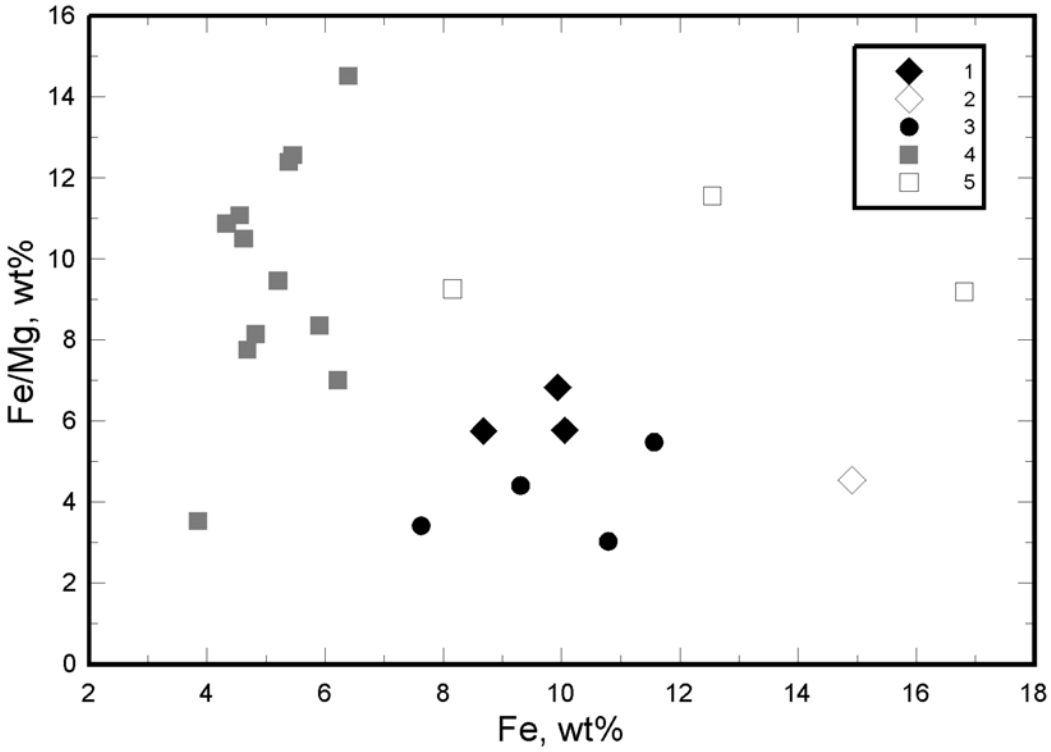

Figure 21. Fe/Mg (wt%) ratios of mineralized rocks of the Anoki Main zone, Kerr Addison flow ore (data from Warwick 1981) and replacement mineralization at the Holloway Mine (data from Ropchan 2000). 1-2, Anoki Main zone (Larder Lake Group, 1-mineralized rocks, 2-unmineralized protolith); 3, Kerr Addison flow ore, Au 19-27 g/t, Larder Lake Group, data from Warwick (1981); 4-5, Holloway Mine (4-mineralized variolitic rocks, Au 1-13 g/t; 5-mineralized Fe-tholeiites, Au 1-12 g/t).

Anoki South Zone

The Anoki South zone is hosted by a unit of siliceous (locally graphitic) interflow exhalites separating massive basalt flows of the Larder Lake Group. The host exhalite horizon strikes east-southeast and dips about 55° south. A 200 m long, 100 m wide and, on average, 3 m thick zone was explored by drilling 250-500 m below surface (Queenston Mining Inc. 2002, 2003). Inferred resources are 0.689 t of gold at an average grade of 6.5 g/t (Queenston Mining Inc. 2003). Mineralization consists of quartz veins and veinlets with visible gold, pyrrhotite, pyrite, chalcopyrite, cubanite and sphalerite. The South Splay constitutes the lower limit of the Anoki South zone (Figure 18). Geochemically, mineralization of the Anoki South zone differs from other gold occurrences of the map area by its distinctly higher base metal (Cu, Zn, Pb, ±Ni) content (Appendix A). This geochemical signature may reflect metal precipitation related to the presence of graphite or carbonaceous matter.

Anoki Deep Zone

The geologic setting of the the Anoki Deep zone is illustrated in Figure 18. Mineralization occurs in a wedge-shaped, south-dipping unit of presumably Timiskaming tuffs, sandstones and conglomerates that are macroscopically different from Timiskaming sandstones and conglomerates exposed further north. Tuffaceous and clastic rocks contain lenses and slivers of ultramafic talc-chlorite and carbonate-fuchsite schists. The South Splay and the Larder Lake Break confine the unit from south and north. Mineralization comprises several intervals of quartz veining enclosed by carbonate-fuchsite-altered ultramafic rocks, or

by carbonatized tuffs and clastic rocks with disseminated pyrite. Mineralization is typically low-grade (1-5 g/t); the best intersection is 30.2 g/t over 4.0 m (www.queenston.ca). The upper contact of the Anoki Deep zone (i.e., the South Splay) constitutes the down-dip limit of Anoki Main and Anoki South zones.

40 East Zone

The 40 East zone is hosted in a band of Timiskaming clastic sedimentary rocks flanked by Larder Lake Group mafic-ultramafic rocks to the south and by Timiskaming alkalic volcanic rocks to the north. The northeast-trending, southwest-dipping zone was traced by drilling over a strike length of 600 m (Queenston Mining Inc. 2003). It comprises quartz-carbonate-feldspar veins and veinlets with 1-3% pyrite and visible gold enclosed in altered sandstones, and, at least in some drill intersections, spatially associated with carbonate-sericite-altered feldspar-phyric dikes or sills. The best intersections include 10.5 g/t over 0.9 m, 16.8 g/t over 2.7 m, and 11.5 g/t over 0.7 m (Queenston Mining Inc. 2003). Petrographic observations on one polished thin section of a strongly sulphidized (pyrite), carbonate-sericite-altered feldspar-phyric rock from the 40 East zone revealed the presence of very small ($\leq$ 0.05 mm) gold particles in pyrite grains and carbonate gangue. Pyrite also contains sphalerite inclusions. Geochemical data for one drill intersection of the 40 East zone are presented in Appendix A.

MCBEAN

McBean mineralization is confined to a band of metamorphosed and hydrothermally altered ultramafic rocks at the southern margin of the Larder Lake–Cadillac deformation zone ("Larder Lake Break", Thomson and Griffis 1941). Numerous syenitic and felsic porphyry dikes constitute up to 50-60 volume % of the unit (illustrations in Bell 1987). Meta-ultramafic schists are flanked by gabbros to the south and by Timiskaming conglomerate and sandstone package to the north. Drilling data indicate that mineralization is spatially associated with a distinct bend in the attitude of the host lithologic units. In the mine area, the strike of the south Timiskaming contact changes from about 120º to about 080º-090º. This is accompanied by a change of dip angle from 75º-80º (southwest) to about 60º (south-southeast) (Figure 22). Mineralized zones have a strike length of about 600 m, they dip steeply south approximately parallel to lithological contacts, and plunge about 50º to the east. Mineralization was traced to 600-650 m below the surface and remains open down plunge. The mineralized zones contain measured and indicated resources of 4.26 t of gold with an average grade of 5.1 g/t, and inferred resources of 11.93 t of gold with an average grade of 6.5 g/t (Queenston Mining Inc. 2003). Gold values correspond to zones of quartz veining enveloped by carbonate-fuchsite schists ("green carbonate ore") and zones of variably intensive bulk alteration and sulphidation of syenite dikes (Bell 1987). The bulk of the ore that was mined from the presently flooded McBean open pit came from low-grade mineralized zones in altered syenite with disseminated pyrite (1.71-5.14 g/t, average 2.98 g/t; Bell 1987). The ore contained fine gold largely associated with pyrite that probably formed by sulphidation of primary magnetite in the dikes (Bell 1987). At deeper levels (below about 300 m depth) explored by Queenston Mining Inc., mineralization includes zones of quartz veining in carbonate-fuchsite schists and volumetrically subordinate quartz-carbonate-sericite-altered aphyric dikes with disseminated pyrite and small quartz veinlets. The grades in these deep zones are typically higher than those in the pit; visible gold in quartz veins was reported in several drill holes. In the present study, mineralization was examined in two drill holes (MB96-19 and MB96-12). Two foliations are observed in carbonate-fuchsite schists enveloping gold-bearing veinlets. The main foliation is defined primarily by compositional banding (i.e., intercalation of mica- and carbonate-rich bands) and is overprinted by discrete crenulation cleavage. Although drill core material provides only general orientation constraints, the two foliations likely correspond to S2 and S4 (Photo 25). Emplacement of gold mineralization and related carbonate-fuchsite alteration probably overlapped in time with S2 formation.

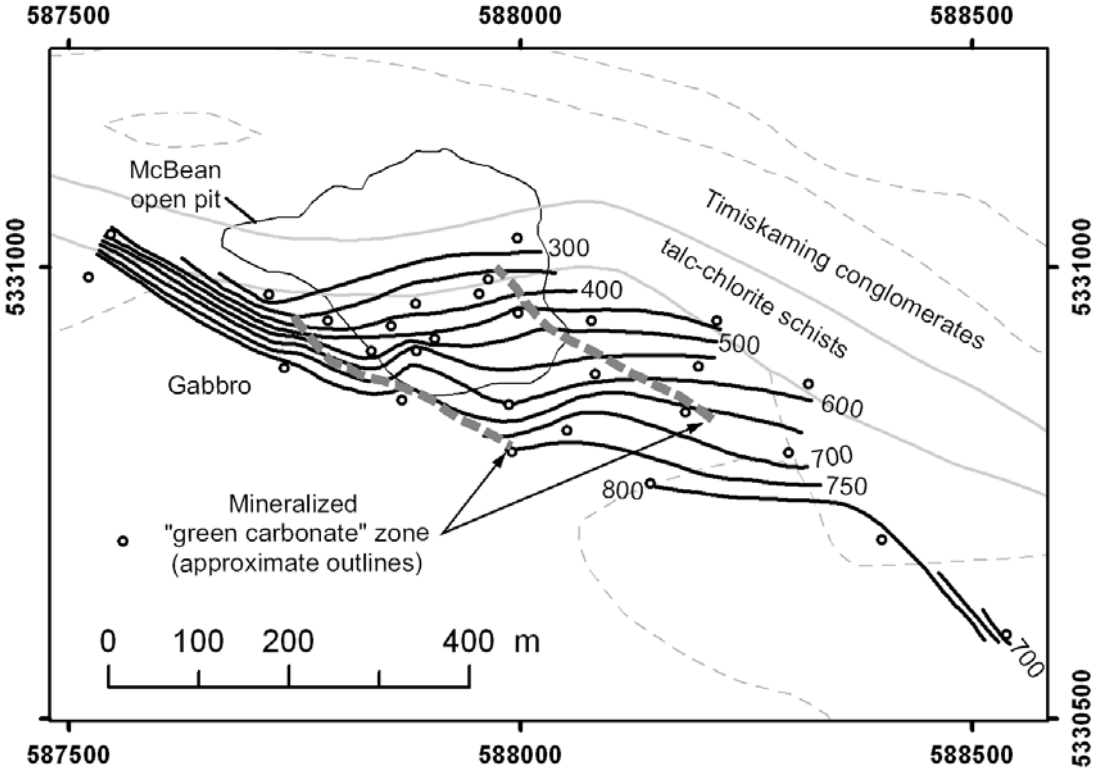

Figure 22. McBean open pit area: contour lines of the south contact of Timiskaming conglomerates (footwall of the McBean mineralized zones) and approximate outlines of the green carbonate mineralized zone (depth about 300-700 m). Numbers depict depth (in m), circles correspond to drill intersections of the contact. Based on Queenston Mining Inc. drilling data.

Photo 25. Drill core from the footwall of the McBean "green carbonate" mineralized zone (hole MB97-19). Photographed interval is located about 20 m down hole from the high-grade mineralization and is itself anomalous in gold (approximately 0.45 g/t). Top: fold closure; folded S2 defined by compositional banding of hydrothermal carbonate, fuchsite, and possibly chlorite. Bottom: axial planar discrete crenulation cleavage that is indistinguishable from S4 in surface outcrops. If hydrothermal alteration is directly related to gold mineralization, the relationships imply that mineralization occurred prior to or was broadly synchronous with D2 and was overprinted by D4.

In addition to the described mineralized zones there are several smaller showings, most of which are depicted on the geological map (see Map P.3546–Revised). Interesting are occurrences along the north flank of the Larder Lake–Cadillac deformation zone marked by a unit of mafic-ultramafic volcanic rocks: e.g., Murphy shaft zone and Princeton ("North Break") (see Map P.3546–Revised for locations). In both cases, mineralization appears to be spatially associated with a contact of Larder Lake mafic-ultramafic volcanics (south) and Timiskaming clastic rocks (north). Although these gold occurrences are economically insignificant, the presence of gold indicates that auriferous fluids were migrating along this part of the deformation zone. Better mineralization could possibly be found at more favourable depositional sites along the north flank of the Larder Lake–Cadillac deformation zone.

GOLD MINERALIZATION ASSOCIATED WITH THE LARDER LAKE–CADILLAC DEFORMATION ZONE IN MCVITTIE AND MCGARRY TOWNSHIPS

Thomson and Griffis (1941) recognized that mineralization of the Anoki and McBean (formerly Queenston) properties corresponds to the western continuation of a regional ore-controlling structure ("Larder Lake Break") that also spatially controls the location of the Kerr Addison-Chesterville, Cheminis, and Omega gold deposits, as well as several smaller occurrences in McVittie and McGarry townships (to the east of the Gauthier map area, Figure 23). The geology of the largest gold deposits associated with the Larder Lake–Cadillac deformation zone is briefly reviewed to further compare it with mineralization of the Anoki and McBean properties.

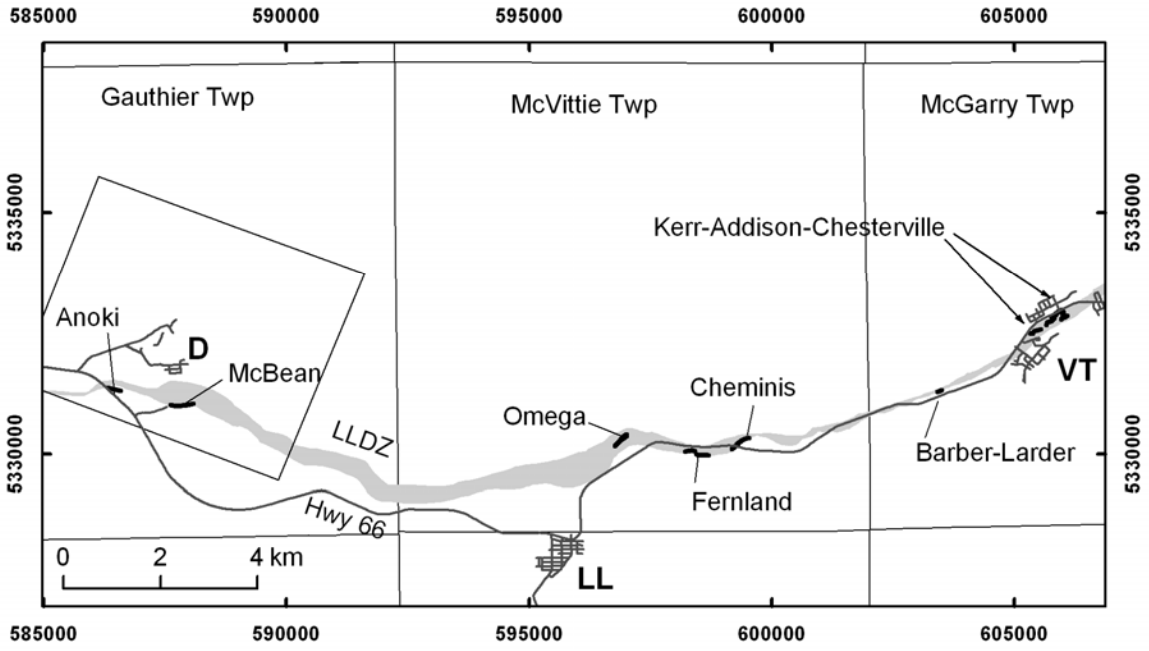

Figure 23. Schematic depicting location of gold deposits and major occurrences along the Larder Lake–Cadillac deformation zone (LLDZ). Abbreviated are town names: D, Dobie; LL, Larder Lake; and VT, Virginiatown. After Thomson (1941) and Smith et al. (1993).

Detailed information is available for the world-class Kerr Addison-Chesterville Mine that produced roughly 332 tonnes of gold (Smith et al. 1993; Kishida and Kerrich 1987). Mineralization is hosted by a mafic-ultramafic sequence of the Larder Lake Group, within the Larder Lake–Cadillac deformation zone. To the north, mineralization is bounded by a sliver of Timiskaming turbidites. The contact of Timiskaming turbidites and Larder Lake Group volcanics trends northeast and dips steeply north (Smith et al. 1993). Gold ore was mined to a depth of 1400 m (Smith et al. 1993). The alteration envelope associated with gold mineralization is tabular, 50-120 m thick, and steeply north dipping. In the longitudinal section view, it has a funnel-like shape, narrowing from 900 m (strike length) at surface to 300 m at a depth of 1700 m, and plunging about 70º to the east (Smith et al. 1993). Most of the gold (230 t Au at 11.0 g/t Au) was produced from replacement-style "flow ore", representing sulphidized, pyrite-rich, Fe-tholeiites and "green carbonate ore" comprised of quartz veins and stockworks in carbonate-fuchsite-altered komatiites (118 t Au at 7.8 g/t; Smith et al. 1993; Kishida and Kerrich 1987). Less significant mineralization types include "albitite ore" consisting of sulphidized dikes, sills and plugs (3 t Au at 3.9 g/t, plus about 5-15% of the green carbonate ore), and "graphitic ore" (sulphidized Fe-tholeiite with graphitic interflow horizons, and mineralized clasts in graphitic gouge of the late-stage Kerr fault, 14.3 t Au at 7.9 g/t; Smith et al. 1993). Mineralization is typically flanked by unmineralized talc-chlorite schists, both along and across the strike (Smith et al. 1993).

The Cheminis and Omega mines are located west of the Kerr Addison Mine, in McVittie Township. Both systems are hosted by the Larder Lake–Cadillac deformation zone, which in that area spatially coincides with a single or branching, 150 to 400 m wide band of intermingled mafic and ultramafic volcanic rocks of the Larder Lake Group, bounded by Timiskaming sedimentary and volcanic rocks to the north and south (Thomson 1941). Mineralized systems are spatially associated with broad S-shaped bends of the mafic-ultramafic belt along the Larder Lake–Cadillac deformation zone. Mineralization occurs along the northeast-trending segments of the mafic-ultramafic band. In both mine areas, lithologic units dip to the south: 70º-80º at Cheminis, and 60º (to 45º at depth) at Omega (Thomson 1941; Clark and Bonnar 1987).

Mineralization at the Cheminis Mine occurs as near-vertically plunging ore shoots, with a strike length of 50-150 m and explored vertical extent of about 1 km (Clark and Bonnar 1987). Based on available descriptions, pyrite-rich replacement of mafic lava and "cherty" tuff comprises the predominant mineralization type (Thomson 1941). Gold occurs as micron-size particles in pyrite; other sulphides include arsenopyrite, sphalerite, pyrrhotite and tetrahedrite (Clark and Bonnar 1987). Variably carbonatized ultramafic talc-chlorite schists flank mineralized zones. Occurrence of less significant "carbonate ore" probably related to quartz veining in carbonatized ultramafic rocks is reported on the website of NFX Gold, present owner of the Cheminis Mine (www.nfxgold.com).

In the Omega Mine, mineralization occurs within a roughly 750 m long zone. Replacement-style mineralization is predominant; gold-bearing quartz stockworks in carbonate-fuchsite-altered ultramafic rocks are minor (Thomson 1941). Pyrite-rich replacement ore is confined to petrographically distinct quartz phenocryst-bearing dacite horizons bordered by sheared and variably carbonatized talc-chlorite schists (Thomson 1941). Subordinate chalcopyrite and arsenopyrite occur in replacement ore along with pyrite. Smaller gold occurrences, e.g., Barber Larder (McGarry Township) and Fernland (McVittie Township), are similarly hosted by the Larder Lake–Cadillac deformation zone and consist mainly of sulphide-bearing replacement zones in volcanic rocks (Thomson 1941).

CHARACTERISTICS OF GOLD MINERALIZATION HOSTED BY THE LARDER LAKE–CADILLAC DEFORMATION ZONE

Gold mineralization at the Anoki and McBean properties is similar to the above-described gold deposits of McVittie and McGarry townships. In particular, the replacement-style, pyrite-rich Anoki Main zone shares strong analogies with the Kerr Addison-Chesterville flow ore, and replacement ores of Cheminis and Omega mines. Gold-bearing quartz stockworks in carbonate-fuchsite schists explored at depth at the McBean deposit and within the Anoki Deep zone are similar to the "green carbonate" ore at Kerr Addison-Chesterville. Mineralized aphyric dikes of the McBean ore zone strongly resemble the albitite ore of the Kerr Addison Mine described by Smith et al. (1993). Mineralization of the Anoki South zone that is hosted by a graphitic exhalite horizon may correlate to the graphite ore of the Kerr Addison-Chesterville Mine. Similarities in mineralization styles as well as analogous structural setting within the Larder Lake–Cadillac deformation zone suggest that gold-bearing zones of the Anoki and McBean properties are likely related to mineralization of Kerr Addison-Chesterville, Cheminis, and Omega mines. All these occurrences of gold mineralization are parts of a single regional hydrothermal system. The most characteristic features of this system are summarized below:

1. Gold mineralization is localized within a first-order structure, that is, the Larder Lake–Cadillac deformation zone (Smith et al. 1993), and (as far as we are aware) there is no tendency for preferential occurrence of larger deposits in second- and third-order structures;

2. Mineralization is commonly associated with gentle S-shaped bends along the Larder Lake–Cadillac deformation zone (Anoki, McBean, Omega, and Cheminis);

3. On the scale of the host deformation zone, mineralization tends to form linear shoots (strike length<dip length) that plunge roughly parallel to the regional stretching lineation (L2): e.g., 40-50° east at McBean (this study); approximately 70º E at Kerr Addison-Chesterville (Smith et al. 1993, p. 30); near vertical at Cheminis (longitudinal section in Clark and Bonnar 1987; structural data in Wilkinson 1993, p.142).

4. At least some mineralized zones are centered on relatively competent lava flow units (e.g., Omega, Cheminis, possibly Kerr Addison) that are flanked by rheologically weak and probably impermeable ultramafic talc-chlorite schists (e.g., Thomson 1941; Smith et al. 1993).

5. There are two principal types of gold mineralization: a) the economically most important style is the pyritic replacement ore where gold is present largely as submicroscopic particles in pyrite (accounts for about 65% of gold at Kerr Addison-Chesterville, most gold at Cheminis and Omega, and Anoki Main zone), and b) the second in importance are quartz stockworks and veins in carbonate-fuchsite-altered ultramafic rocks, where coarser gold is present principally in quartz. The two mineralization types coexist within individual deposits and are probably related to the same hydrothermal episode (e.g., Smith et al. 1993). Localization and shape of individual replacement ore bodies is typically defined by primary or structurally modified geometry of geochemically and rheologically favourable units (Smith et al. 1993; present study of the Anoki Main zone). Volcanic rocks of the Larder Lake Group constitute the most common protolith for replacement ores. Volcanic protoliths of the Anoki Main zone and Kerr Addison-Chesterville flow ore (Warwick 1981; Kishida and Kerrich 1987) are Fe-tholeiites. Carbonate is the major component in both mineralization types, which indicates that ore was generated by carbonic, CO_2 – rich fluids (e.g., Kishida and Kerrich 1987). Sulphidation of the Fe-rich, high Fe/Mg tholeiitic rocks must have constituted the main gold deposition mechanism for pyritic replacement mineralization (Böhlke 1988; Phillips et al. 1984; Smith et al. 1993), whereas relatively coarse gold in quartz veins enclosed in carbonate-fuchsite alteration was most likely deposited through phase separations (e.g., Smith et al. 1993). The latter mechanism agrees well with the rather irregular distribution of gold in "green carbonate

ore" (Smith et al. 1993) and occurrence of gold-barren quartz stockworks in carbonate-fuchsite schists. Both types of mineralization most probably belong to the syn-deformation greenstone-hosted quartz-carbonate vein (mesothermal-orogenic) deposit class.

6. Syn-mineralization hydrothermal alteration likely increased competency of host rocks; ultramafic talc-chlorite schists were modified into carbonate-fuchsite rocks with abundant quartz veining, the largely chloritic flow unit of the Anoki zone was replaced by albite-rich aggregate. In both cases, hydrothermal products are more rigid than the protolith, and are likely to respond more brittley to continuing deformation and maintain or even enhance permeability.

Occurrence of mesothermal gold mineralization in the first order deformation zone is unusual. Within the most economically significant gold camps, the largest gold deposits are typically found in subsidiary second- and third-order structures (e.g., Eisenlohr et al. 1989; Robert 1990; McCuaig and Kerrich 1998). This atypical localization pattern may be due to the nature of the Larder Lake–Cadillac deformation zone in the Larder Lake area. Lithological assemblage of the Larder Lake–Cadillac deformation zone includes competent mafic volcanic units intermingled with or enveloped by incompetent and impermeable ultramafic talc-chlorite schists (Thomson 1941). This combination probably constituted favourable ground for maintaining isolated discrete permeable fluid conduits within the deformation zone. Competent tholeiitic volcanic units responded more brittley, thus enhancing their overall permeability. Rheologically weak talc-chlorite schists enveloped these permeable zones, preventing fluid dispersal and maintaining high fluid/rock ratios within fluid pathways. Some of these competent units were also geochemically favourable for sulphidation (e.g., Fe-tholeitic, high Fe/Mg rocks), and gold deposition occurred.

The location of gold deposits in the Larder Lake–Cadillac deformation zone may (at least in part) reflect biases in exploration strategies, that is, the "Larder Lake Break" has for almost 100 years attracted the most attention from geologists and prospectors alike, and potentially gold-bearing subsidiary structures may have been overlooked. There is no geological factor precluding the occurrence of gold mineralization along subsidiary faults or shear zones that were hydraulically connected to the Larder Lake–Cadillac deformation zone during a regional hydrothermal mineralizing event. The presence of Fe-tholeiites in the Kinojevis assemblage and Larder Lake Group (north and south of the Larder Lake–Cadillac deformation zone) supports the possibility for formation of replacement-style gold mineralization along subsidiary splays of the Larder Lake–Cadillac deformation zone.

Relationships of Gold Mineralization in the Larder Lake–Cadillac and Upper Canada Deformation Zones and Structural Timing of Mineralization

Are the gold deposits along the Larder Lake–Cadillac and Upper Canada deformation zones genetically related? A definite answer to this question requires more detailed knowledge of fluid compositions (e.g., Neumayr and Hagemann 2002). However, our data suggest close relationships between gold occurrences in the two deformation zones. The Upper Canada deformation zone is probably a splay of the Larder Lake–Cadillac deformation zone, both zones are syn-D2 and could be hydraulically connected. In both deformation zones, mineralizing fluids were CO_2 -rich (i.e., carbonic), which resulted in carbonate-rich alteration assemblages at the Upper Canada, Anoki, McBean, and other gold deposits of Larder Lake–Cadillac deformation zone. The plunge of ore zones at the Upper Canada, McBean, Cheminis, and Kerr Addison is approximately parallel to stretching lineation L2. There are differences in the metal inventories of the different mineralized zones (Appendix A), but they are relatively minor and do not preclude a possible linkage between gold occurrences.

Syn-D2 introduction of gold is documented in the "L" mineralized zone of the Upper Canada Mine. For mineralization hosted by the Larder Lake–Cadillac deformation zone, the structural timing data are not so definitive. However, relationships between alteration and deformational fabrics in McBean drill core, and the likelihood of close relationships between mineralization in the two deformation zones, imply that gold mineralization hosted by Larder Lake–Cadillac deformation zone could also be broadly synchronous with D2.

Summary of Factors Controlling the Distribution of Gold Mineralization

All the gold deposits and occurrences discussed above occur in syn-D2 ductile deformation zones. The order of deformation zones does not appear to be a major controlling factor, at least as seen from the distribution of presently known deposits. Most deposits occur in northeast-trending structures, however there are exceptions and, more importantly, there is no indication that a northeast orientation is essential for the localization of gold deposits. In the Larder Lake–Cadillac deformation zone, some gold occurrences are spatially associated with bends along the host structure or lithological contacts within it. The setting of the Upper Canada mineralization may have been partially controlled by the syenite porphyry intrusion and the contact between the volcanic and turbiditic units. Geochemically favourable lithologies, such as Fe-tholeiites in Anoki Main zone and Kerr Addison flow ore, acted as chemical traps for replacement-style gold mineralization via host rock sulphidation. The presence of graphite or carbonaceous matter at the Anoki South zone could have assisted in the deposition of gold by changing the redox conditions of auriferous fluids. For other observed types of gold mineralization, host lithologies are unlikely to have directly controlled the gold deposition.

Teck Township Transect

The 36 km^2 transect includes the town of Kirkland Lake, and the area immediately west of it, south and north of the Highway 66 (Map P.3558, back pocket). The area is underlain from north to south by mafic volcanic rocks of the Kinojevis assemblage, clastic sedimentary rocks and alkalic volcanic rocks of the Timiskaming assemblage, and mafic volcanic rocks of the Tisdale assemblage intruded by the Murdock Creek pluton (Ayer et al. 2002). In this project, major ore-controlling structures were examined underground and mapped at surface at a scale of 1:10 000. Mapping was conducted mainly north of Highway 66 and was focused on Timiskaming assemblage rocks; only a few Tisdale and Kinojevis rock outcrops were examined. In addition, structural data were collected along the southern contact of the Timiskaming assemblage south of the town of Kirkland Lake.

GENERAL GEOLOGY

A description of the geology of the Kirkland Lake area can be found in Todd (1928), Thomson (1950), and Lackey (1990), and more detailed discussion of specific stratigraphic assemblages and units are presented by Hyde (1978, 1980), Lackey (1990), Mueller et al. (1994), and Legault and Hattori (1994a,b). The geology of the Kirkland Lake deposit is described by Todd (1928), Thomson et al. (1950), Charlewood (1964), Watson and Kerrich (1983), Watson (1984), Kerrich and Watson (1984), Lackey (1990), and Still (2001). The following brief description addresses only aspects of the geology that are relevant to the present study.

The Kinojevis assemblage underlies the northern part of the map area and consists of north-facing pillowed basalts and coarser gabbroic or dioritic rocks interpreted as intrusions or coarser flow units (Thomson 1950). North-facing Kinojevis volcanic rocks are unconformably overlain by Timiskaming sedimentary and volcanic rocks that form a 3 km wide northeast-trending band. Thomson (1950) documented the unconformable nature of the lower Timiskaming contact. In this project, the partially exposed unconformable north contact of the Timiskaming assemblage was observed in the newly stripped outcrops on the Marion-Boyce properties north of the town of Kirkland Lake. There, the north-facing pillow basalts of the Kinojevis assemblage are overlain by a roughly 4-5 m thick layer of basal breccias, consisting largely of angular clasts (1-3 cm to 20-75 cm) of the underlying basalts. Large (20-50 cm) pillow fragments can be unequivocally recognized by well-defined pillow rims. The breccias are interlayered with thinly (2-3 mm) laminated siltstones, and further up-section (southward) they are overlain by interlayered sandstone-siltstone.

With the exception of a small area west of Gull Lake, the Timiskaming rocks face south and dip steeply to moderately (approximately 50-70º) to the south (Thomson 1950). Alluvial-fluvial (e.g., Hyde 1980; Mueller et al. 1994) sandstones and conglomerates are volumetrically predominant in the Timiskaming assemblage. Corfu et al. (1991) reported a <2680±3 Ma U-Pb detrital zircon age for Timiskaming sandstone from the central part of the map area. Volcanic rocks include three major alkalic pyroclastic units named (from north to south): Grenfell, Goodfish, and Blanche River formations (Hyde 1978; Lackey 1990). The unit in the middle (Goodfish Formation of Lackey 1990) is disrupted and "duplicated" at surface by the Kirkland Lake fault (e.g., Todd 1928; Thomson 1950; Lackey 1990). To the south, Timiskaming rocks are bounded by the mafic-ultramafic volcanic rocks of the Tisdale assemblage. The latter are intruded by the 2672±2 Ma Murdock Creek pluton (Wilkinson et al. 1999).

The Larder Lake–Cadillac deformation zone corresponds to the southern margin of the Timiskaming assemblage (Wilkinson et al. 1999). About 2 km to the north, syenitic stocks are cut by the Kirkland Lake fault or Main Break, a brittle to brittle-ductile fault that strikes roughly 65º and dips steeply to the south. Gold mineralization of the Kirkland Lake deposit generally occurs along this fault and its immediate splays. Mineralization comprises relatively sulphide-poor quartz veins, with gold and associated tellurides occurring mostly in the veins rather than in the altered host rocks. In the currently active Macassa Mine at the western end of the camp, the main ore-controlling structure is the '04 Break. The '04 Break is a northeast-striking fault, which is parallel to and located 120-140 m north of the Main Break (Charlewood 1964; Still 2001). Ore-controlling faults and auriferous quartz veins are offset by major post-ore faults, including the Amikougami Creek, Tegren, Lake Shore, and Sylvanite faults (Thomson et al. 1950). No economic mineralization has been found to date west of the Amikougami Creek fault. Other significant faults include the northeast-trending Amalgamated Kirkland–Blanche River and Murdock Creek faults. The moderately (approximately 045º) north-dipping No. 5 fault exposed in underground workings of the Wright-Hargreaves Mine and apparently corresponding to the Murdock Creek fault at surface offsets the Main Break with a reverse sense of movement (i.e., north side up, about 125 m horizontal and about 150 m vertical components; Thomson et al. 1950; Hopkins 1940).

The history of gold discovery and production is discussed in detail in Thomson et al. (1950), Charlewood (1964) and Still (2001). Production commenced in 1915, and through the 20th century, the Macassa, Kirkland Lake Gold (later Kirkland Minerals), Teck-Hughes, Lake Shore, Wright-Hargreaves, Sylvanite and Toburn mines collectively produced 758.3 metric tonnes of gold from 49 862 868 tonnes of ore with an average grade of 15.21 g/t (Gosselin and Dube 2005). Gold was mined from one giant Kirkland Lake gold deposit. In the central part of the camp, underground workings extend to about 2.5 km below the surface, and mineralization remains open to depth (Charlewood 1964). Production-based (1913-1962) gold to silver ratio averages 5.4:1 for the entire camp, with the highest, 9.0:1, at Kirkland Lake Gold (Kirkland Minerals) and the lowest, 4.2:1, at Toburn (Charlewood 1964). At present, Kirkland Lake Gold Inc. owns the Macassa, Kirkland Minerals, Teck-Hughes, Lake Shore, and Wright-Hargreaves

properties and produces gold from Macassa number 2 and 3 shafts and Lake Shore ramp (www.klgold.com). Operations at Macassa, where most underground observations were made during this project, presently extend from the 3400-foot to the 5000-foot level. The Amikougami Creek fault constitutes the western limit of presently known economic gold mineralization of the Kirkland Lake gold camp. On the east side of the fault mineralization extends vertically for about 1250 m (2900 to 7050-foot levels, M. Sutton and S. Carmichael, Kirkland Lake Gold Inc., personal communication, 2005) and is open at depth.

In addition to the Main Break and '04 Break mineralization (i.e., Kirkland Lake gold deposit), there are several smaller gold deposits and occurrences, including Amalgamated Kirkland (Stevenson et al. 1995), Federal Kirkland, Florena, and Hudson Rand (Kirkland Gold Rand, Thomson 1950). The geology and gold mineralization of these properties are not discussed in this report; most shaft sites are shown on the accompanying geologic map (Map P.3558, back pocket).

INTRUSIVE ROCKS

This section describes igneous rocks of the Kirkland Lake composite stock that hosts gold mineralization, and of smaller bodies intruding the Timiskaming assemblage in the general proximity to the Kirkland Lake fault (Main Break) and in the area north of it. The large Murdock Creek pluton located south of the Larder Lake–Cadillac deformation zone was not examined in this project and is not discussed here.

The petrography of the intrusive rocks was previously described by Todd (1928), Thomson (1950), Watson (1984), Hicks and Hattori (1988), and Hattori and Levesque (1989); the geochemistry was characterized by Watson (1984), and Kerrich and Watson (1984). The descriptions presented below are based on original observations of this study. The geochemistry of the intrusions is briefly illustrated in the section on intramineral dikes.

Alkalic igneous rocks are subdivided into three phases (from the earliest to the latest phase): mafic (augite) syenite; syenite; and syenite porphyry. Mafic (augite) syenite forms the western part of the composite stock transected by the Main Break, and a large, up to 350 m wide, body 500-800 m north of the Main Break. The two bodies apparently join at depth (e.g., Charlewood 1964). Mafic syenite consists of pyroxene (augite), K-feldspar, locally biotite, and minor plagioclase. Visually estimated percentage of augite varies from 25 to 60%. In most locations, pyroxenes are to a variable extent replaced by chlorite and carbonate. Most augite syenites are near equigranular (2-5 mm grain size); porphyritic varieties with augite phenocrysts and fine-grained, feldspar-rich groundmass were observed in small dikes in the northwest part of the area (north of the railway). Hydrothermally altered mafic syenite has a characteristically spotty appearance defined by dull-green to greenish light grey pseudomorphs after pyroxene set in a red, K-feldspar-rich matrix. A distinct characteristic of augite syenite is the presence of 0.5-1 cm to 10-20 cm thick leucocratic band-like inclusions informally called "felsic ribs". Texturally, these inclusions vary from aphanitic to coarse-grained, the latter consisting of long-prismatic K-feldspar (3-5 mm). The constant presence of leucocratic bands marks the originally anisotropic nature of the mafic syenites and existence of primary (magmatic) planar fabrics in the intrusions. An example of such fabric is shown in Photo 26, from the Narrows Break stripped outcrop, where closely spaced (10-15 cm) thin felsic ribs are oriented parallel to the contact of the intrusion. Some gold-bearing quartz veins at the Macassa Mine are oriented approximately parallel to these "felsic ribs" indicating that vein-hosting fractures could have exploited primary anisotropy of the intrusions (Photo 27). Sharp contacts between the mafic syenite intrusions and host sedimentary and pyroclastic rocks were observed in several locations. Although the contacts are undoubtedly intrusive, and bedding is commonly truncated on a small scale, the overall orientation of observed contacts is approximately parallel to bedding in the Timiskaming rocks.

Syenite constitutes a relatively minor rock type, which forms an irregular pipe-like body exposed along the Main Break on the Teck-Hughes and Lake Shore properties. It plunges 30º to 40º southwest. The upper contact of this pipe-like body approximates the upper boundary of the Main Break gold mineralization from the former Kirkland Lake Gold shaft #1 to Macassa shaft #1. Typical syenite is a hollocrystalline rock consisting almost entirely of randomly oriented subhedral to anhedral prismatic K-feldspar; varieties that are transitional to mafic syenite may contain up to 20% pyroxene. In addition to the pipe-like syenite intrusion exposed on the Teck-Hughes property, a narrow body of syenite was mapped roughly 550 m north of the Main Break, along the contact of a large mafic syenite intrusion. Syenite in that location contains approximately 15% pyroxene and probably represents a rock type transitional to mafic syenite. Todd (1928) reported sharp intrusive contacts between syenite and mafic syenite, and Watson (1984) described both sharp and gradational contacts.

Syenite porphyries form a 2 km long by 0.5 km wide body that underlies the northern part of the town of Kirkland Lake and hosts gold mineralization at the former Lake Shore, Wright-Hargreaves, Sylvanite, and Toburn mines. In addition to this large intrusion, syenite porphyries occur as numerous smaller dikes, sills and stocks throughout the map area. Two textural varieties were identified during mapping; for descriptive purposes they are named “feldspar-rich” and “sparsely porphyritic”. Apart from rare exceptions, these two varieties are macroscopically distinct, and can be mapped as separate rock types, however they are not distinguished on Map P.3558. This is because systematic re-mapping of intrusive phases was not among the main objectives of this project, and only a few syenite porphyry intrusions were examined.

Photo 26. Outcrop of mafic syenite on the Narrows Break stripped outcrop. Magmatic foliation defined by thin (0.5-2 cm) feldspathic bands (“felsic ribs”) spaced at 15-30 cm and oriented approximately parallel to the contact of the intrusion.

Photo 27. North wall of stope 4225, Macassa Mine. In the upper part of the photograph, note the large leucocratic band ("felsic rib", maximum thickness approximately 30 cm) in mafic syenite. Quartz veins have a similar orientation indicating that vein-hosting structures may have been exploiting primary anisotropy of intrusive rocks.

"Feldspar-rich" syenite porphyry is a massive rock that contains 30-50% fine (1-2 mm to 3-4 mm), short prismatic to subequant plagioclase phenocrysts along with 5-10% biotite, and less commonly amphibole. Also characteristic is the presence of green angular aphanitic xenoliths, presumably of mafic volcanic rocks (Photo 28). The presence of xenoliths is so typical that it is used by mine geologists as a diagnostic feature to distinguish syenite porphyries from syenites in underground workings throughout the camp. Our observations indicate that the main intrusive body of the Kirkland Lake stock (hosting Wright-Hargreaves, Sylvanite and Toburn mineralization), and associated dike-like apophyses probably consist of this rock type, although not all exposures of the main intrusive body were examined. In addition to the main stock, a smaller, 700 by 100 m intrusion immediately west of the former Kirkland Lake, south of the railway and about 400 m north of the Main Break, also consists of this syenite porphyry variety.

Sparsely porphyritic syenite porphyries differ from feldspar-rich varieties by lower feldspar phenocryst contents (5-15 to 20%, Photo 29), their larger size (1-5 mm), and by a significantly higher percentage of mafic minerals (20-35%), represented mainly by amphibole (0.25-1 mm, to 3 mm locally) and subordinate biotite. Very melanocratic syenite porphyries, with up to 50% amphibole and 5-15% feldspar, form a 100-200 m wide elongate intrusive body stretching roughly parallel to and 200-250 m south of the Timiskaming-Kinojevis contact, east and west of the Amikougami Creek fault. In addition to green aphanitic xenoliths, sparsely porphyritic syenite porphyries also contain rounded (pebble- to cobble-like) granitoid xenoliths that are 5 to 20 cm in diameter (Photo 30). Xenoliths of high-grade crystalline schist and vein quartz (1cm by 3 cm) were observed in one locality. Direct relationships between the two varieties of syenite porphyry were not observed. Dikes of "feldspar-rich" syenite porphyry crosscut mafic syenite and syenite bodies.

Photo 28. Feldspar-rich syenite porphyry with a chloritic xenolith. Note high percentage of fine-grained feldspar phenocrysts (white). Coin diameter is approximately 2.5 cm.

Photo 29. Sparsely porphyritic variety of syenite porphyry, coin diameter is approximately 2.5 cm.

Photo 30. Pebble-like leucocratic granitoid xenolith in sparsely porphyritic syenite porphyry.

A somewhat different variety of feldspar-phyric rocks was observed on a small peninsula along the west shoreline of the former Kirkland Lake, about 450 m north of the railway. The rock has a light green matrix and contains about 20% feldspar phenocrysts (1-5 mm). It is non magnetic, whereas typical syenite porphyries are moderately magnetic. On the map by Hopkins (1949, plate 1) this rock is depicted as granite porphyry. Most exposures of the granite porphyry are to the east of former Kirkland Lake, where the rock forms a 100-200 m wide east-northeast-trending body. It is probably the equivalent of a quartz-feldspar porphyry body uncovered by a long north crosscut at the 3075-foot level at the Lake Shore Mine (Thomson et al. 1950, p.151). Outcrops on the east side of the former Kirkland Lake were not examined in this project. On the accompanying geologic map (Map P.3558), the rocks are shown as syenite porphyries (as compiled from Thomson 1945), however, they almost certainly represent a separate intrusive phase.

A distinct rock type occurs north of Highway 66, immediately west of Amikougami Creek. This porphyritic rock contains prismatic phenocrysts of feldspar and pyroxene set in an aphanitic groundmass. The rocks form a 300 m wide southwest-trending body that reportedly has an intrusive contact with host tuffs (Thomson 1950). On Map P.3558, the rock is described as trachyandesite based on field identification. Geochemically, these rocks are very similar to mafic syenites and may represent their hypabyssal equivalent (see geochemical plots in a section describing intramineral dikes). Other intrusive rocks include coarse biotite lamprophyres, Matachewan diabase dikes and intramineral dikes (the latter are discussed in a separate section).

The shapes of alkalic intrusions were previously discussed by Thomson et al. (1950). The ore-hosting composite intrusion which consists from west to east of mafic syenite, syenite and syenite porphyry is aligned approximately parallel to the host stratified units. Its south contact dips more shallowly than the northern contact, and the body widens with depth (Thomson et al. 1950). Near Macassa shaft #1, the steeply (roughly 75-80º) dipping mafic syenite intrusion crosscuts more shallowly

south-dipping tuffs and conglomerates, however the dip of the southern contact becomes more shallow below the 2000-foot level, and the body widens to the south at deeper levels (Thomson et al. 1950). As can be judged from cross sections, Main Break ore does not occur in the upper, narrow and steep portion of the intrusion (e.g., Thomson et al. 1950, sheet A, cross-section 2).

The geometry of a large mafic syenite intrusion that hosts mineralization in the central-western parts of the camp can be interpreted as a combination of a larger (200-250 m wide on surface) approximately concordant part and relatively narrow (50-80 m) northeast-trending (roughly 060-070º), steeply south-dipping (roughly 80º) apophyses that are generally discordant to the host rocks (Figure 24). The western boundary of the syenite pipe-like body corresponds to the base of the discordant apophysis. This geometry is important for the distribution of gold mineralization because the western (i.e., upper in cross-section view) limit of the wider part of the mafic syenite intrusion and of the syenite pipe-like body in the hanging wall of the Main Break approximately coincide with the upper boundary of gold mineralization at the Kirkland Lake Gold Mine and the eastern part of the Macassa Mine. A smaller syenite porphyry body approximately 400 m north of the Main Break in the same area also appears to consist of a near-concordant larger portion and a narrow discordant northeast-trending apophysis (Figure 24).

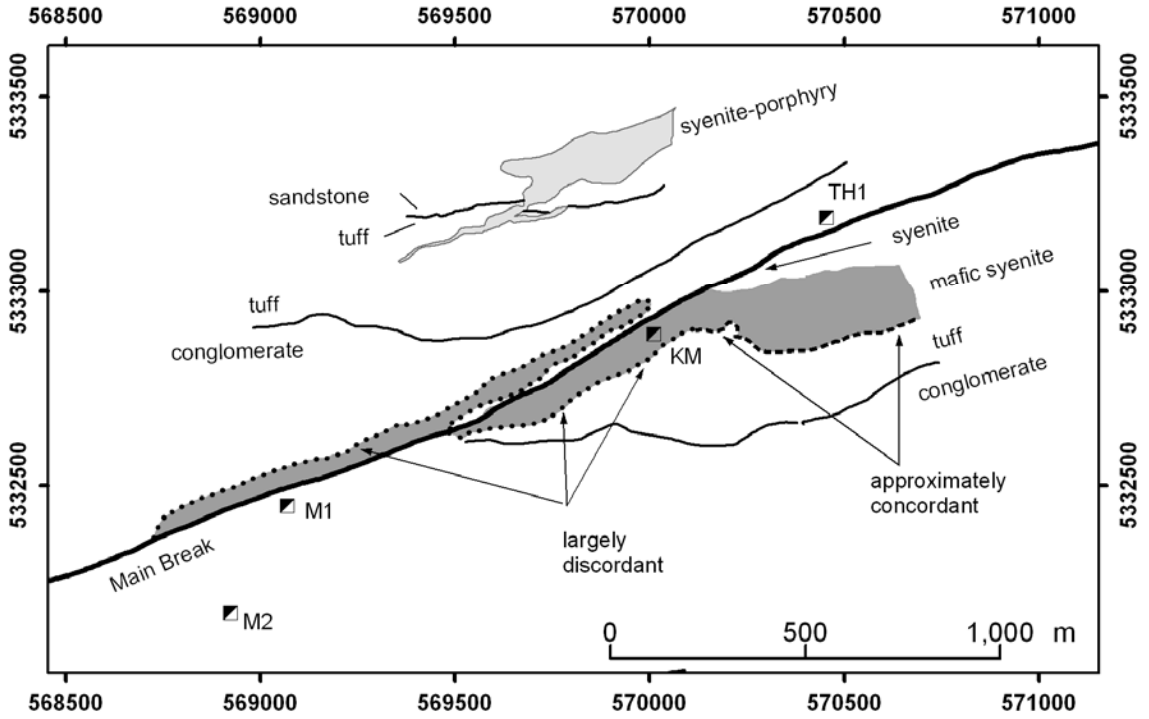

Figure 24. Relationships of the mafic syenite intrusion and stratigraphic units in the central part of the Kirkland Lake camp. The intrusion consists of a larger, approximately concordant portion (note the orientation of south-southwestern contact of the intrusion and tuff-conglomerate contact) and narrow northeast (approximately 070º)-striking apophyses that are discordant (approximately 20-25º counterclockwise) with respect to the roughly east-west-trending stratigraphic contacts. The south-southwest contact of the larger (approximately concordant) part of the intrusion plunges (30-40º) westward. The smaller syenite porphyry intrusion north of the Main Break shows similar geometry: a larger body with near concordant southern contact and a narrow northeast-trending apophysis oriented 20-25º counterclockwise to the stratigraphic contacts. Selected shafts shown for reference: M1 and 2- Macassa #1 and #2; KM-Kirkland Lake Gold Main shaft; and TH1- Teck-Hughes #1 shaft.

DEFORMATIONAL FABRICS

Compared to the Gauthier transect area, rocks in the Teck Township transect are characterized by generally lower strain and weaker development of penetrative deformational fabrics. S2, the earliest deformation fabric present in Timiskaming rocks, is only developed within or in the immediate proximity of the Larder Lake–Cadillac deformation zone at the contact between Timiskaming sedimentary rocks (conglomerates, sandstones, and siltstones) and volcanic rocks (tuffs) and Tisdale assemblage mafic-ultramafic volcanic rocks (south of the map area). S2 strikes 070º to 110º, dips 70º to 80º to the south, and tends to mimic the orientation of the Larder Lake–Cadillac deformation zone (Figure 25). It is a penetrative foliation defined by flattened clasts in conglomerates (Photo 31) and tuffs and by alternating chlorite, sericite (± fuchsite) and carbonate layers in mafic-ultramafic volcanic rocks. A steeply (about 70º) east-dipping stretching lineation is locally associated with S2 in conglomerates.

S3 was documented only in the chlorite-fuchsite-carbonate-altered ultramafic rocks of the Tisdale assemblage. It is expressed as a north-trending (350º to 005º) cleavage dipping moderately to steeply (50º to 80º) to the east and axial planar to east-southeast-plunging symmetric and Z-asymmetric folds of S2 (Figure 25, Photo 32). Many of these folds do not have an axial-planar cleavage. No unequivocal overprinting relationships with S4 were documented in the Teck Township map area, and the north-south-trending fabric was assigned to S3 based on similarity in orientation with the S3 foliation of the Gauthier Township transect.

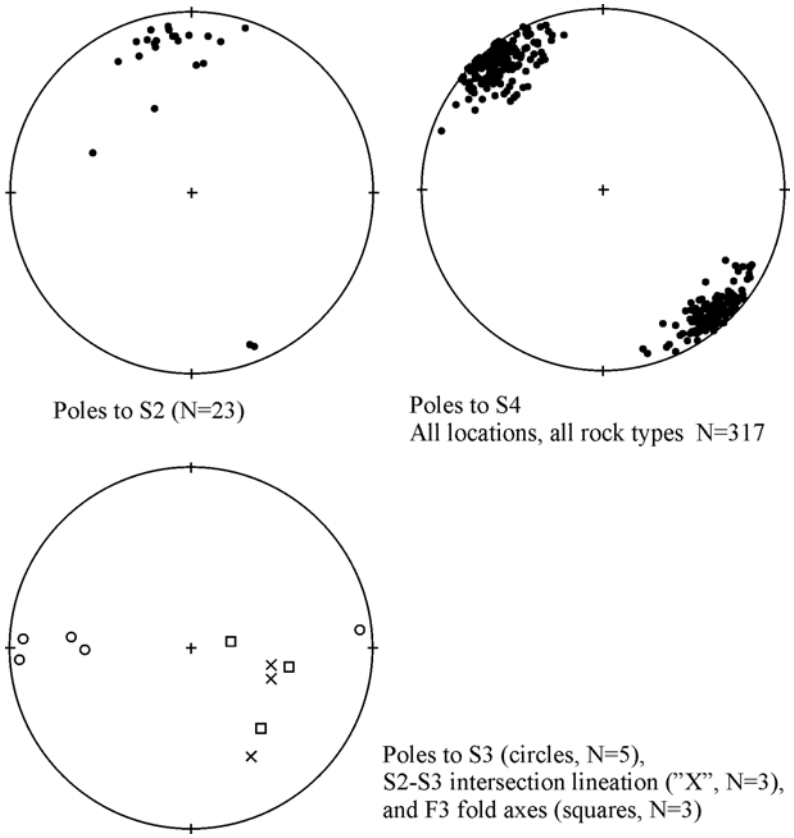

Figure 25. Deformational fabrics of Teck Township transect: S2 (along the Larder Lake–Cadillac deformation zone), S3 (+S2-S3 intersection lineation and F3 fold axes), and S4.

Photo 31. S2 (parallel to the solid line) defined by flattened pebbles in Timiskaming conglomerates (elongate white lenses in the upper part of the photograph) and overprinted by weakly developed S4 (parallel to the dashed line). Southeastern part of the Teck Township transect area (station 004VOI1590). Pencil (15 cm) for scale.

Photo 32. F3 fold with north-south-trending axial plane in carbonate-altered meta-ultramafic rocks. Southeast of the Teck Township transect area (station 004VOI1589). Pencil (15 cm) for scale.

S4 is the most common deformation fabric in the Timiskaming rocks. It consistently strikes 040 to 065º and dips steeply southeast or northwest (Figure 25). Along the Larder Lake–Cadillac deformation zone, S4 is a spaced crenulation cleavage overprinting S2 (Photo 31). North of the deformation zone, development of S4 is uneven. In the center of the map area (i.e., from about 200 m south of the Kirkland Lake fault to the Blanche River–Amalgamated Kirkland–Murdock Creek faults), S4 is relatively weakly developed. Further north, S4 is present again. In bedded tuffs, S4 occurs as spaced disjunctive cleavage, in places axial planar to poorly developed, southwest-plunging folds (Photo 33). Well-developed folds are only rarely observed. Most commonly, there is a long (northwest-trending) limb transected by counterclockwise-oriented S4, and a hinge portion with near orthogonal S4. Instead of the second, southwest-trending limb, the hinge is disrupted (Photo 34) and offset by a single or several tightly spaced shear surfaces parallel to S4 or trending roughly 020º. This pattern is again followed by northwest-trending bedding and counterclockwise-oriented S4. Bedding-S4 intersection lineation plunges moderately southwest, except in the area near the railroad – Goldthorpe road intersection, where the plunge becomes more shallow (15º-20º), and opposite (northeast) plunge directions are noted locally. In conglomerates, S4 is defined by weak to moderate pebble flattening (Photo 35). Fe-carbonatized mafic volcanic clasts are typically more strained than other clast types. Weakly to moderately developed S4 is also observed in mafic (augite) syenite, and sparsely porphyritic varieties of syenite porphyry. Based on simple visual comparison, the highest intensity of D4 deformation (compared to other rock types and locations) appears to occur in the band of conglomerates south of the Timiskaming–Kinojevis assemblages contact and north of the large mafic syenite intrusion (north of the railway).

Photo 33. Disjunctive cleavage S4 in Timiskaming tuffs. Pencil (approximately 15 cm, left-hand bottom) for scale. Narrows Break stripped outcrop, about 350 m north of the Main Break (station 004VOI1531).

Photo 34. F4 folding in tuffs (plan view, facing southwest). Photographed is a transition from the west-northwest-trending limb (lower left-hand, S4 is oriented counterclockwise to bedding) to the hinge portion (S4 at high angles to bedding). In the hinge, bedding planes (solid white lines) are disrupted by shear surfaces (white dashed line) that are parallel or near parallel to axial planar S4. Further northwest from the photographed hinge portion, bedding planes again trend northwest and are transected by counterclockwise-oriented S4, i.e., there is practically no southwest-trending limb with S4 oriented clockwise to bedding. Narrows Break stripped outcrop, station 004VOI1467.

Photo 35. S4 defined by pebble flattening in Timiskaming conglomerates (approximately 1 km north of the Main Break, station 004VOI1562). Cross-section view facing northeast, white tag (upper right-hand) is 17 cm wide.

DEFORMATION ZONES

Larder Lake–Cadillac Deformation Zone

The Larder Lake–Cadillac deformation zone corresponds to the southern contact of Timiskaming sedimentary and pyroclastic rocks with mafic-ultramafic volcanic rocks of the Tisdale assemblage. The deformation zone does not have sharp geological boundaries, and is defined mainly by the intensity of the deformation and occurrence of the S2 foliation. In the present project, structural observations within the Larder Lake–Cadillac deformation zone were made mainly in the southeastern part of the area, where the Timiskaming–Tisdale assemblages contact changes orientation from northeast (near the eastern border of Teck Township) to approximately east-west (western part of Lebel Township). The estimated width of the deformation zone in this area is 400-500 m, although delineating the northern limit of the zone is somewhat difficult, especially in areas where S2 and S4 have similar orientation. The overall intensity of deformation of the Larder Lake–Cadillac deformation zone in Teck Township transect is weaker compared to Gauthier Township. In addition to the development of S2, and similar to the Gauthier Township transect, the deformation zone is marked by bulk carbonatization, especially of ultramafic rocks. Quartz-iron-carbonate veins accompanied by wall-rock carbonatization occur locally in the Timiskaming sandstone-conglomerate package. S2-parallel quartz veins up to roughly 20 cm thick are exposed at the intersection of the powerline and the ATV trail near the southeast corner of the map area. The veins are boudinaged parallel to S2, and subsequently overprinted by S4, implying that they were emplaced before or during D2 deformation. No information on gold grades is available, but the obvious lack of exploration interest indicates that these veins are probably not gold-bearing. No distinct asymmetric shear-sense indicators were observed in the Larder Lake–Cadillac deformation zone in the Teck Township transect area.

Possible Shear Zone South of the Timiskaming Unconformity

Another predominantly ductile deformation zone (possibly a suite of several shear zones) may be located in the north of the map area, between the Timiskaming unconformity and the large mafic syenite intrusion. It occurs mainly in conglomerates and is oriented approximately parallel to the unconformity. Although surface exposures are insufficient to precisely delineate this deformation zone, there are several lines of evidence supporting its existence. Highly strained conglomerates are observed in a fragmental outcrop on the Casakirk property, approximately 70 m northeast of the former Abba shaft. Rocks exposed in stripped outcrops on Marion-Boyce properties (north of the town of Kirkland Lake) and corresponding to the lowermost part of the Timiskaming assemblage are characterized by stronger than average S4 foliation, iron-carbonatization and quartz veining. A long north crosscut at the 3075-foot (approximately 940 m) level at the Lake Shore Mine uncovered a 50 m wide zone of strongly carbonatized and sheared conglomerates, with barren quartz veins about 100-150 m south of the Timiskaming unconformity (Thomson et al. 1950, p.83). Hopkins (1949) reported that this zone was also intersected by surface diamond drilling. Drilling from a long north crosscut at the 3000-foot level at the Macassa Mine also revealed a zone of strongly sheared conglomerates (Thomson et al. 1950). If these occurrences of deformed rocks constitute a single shear zone, most probably it corresponds to D4, since the deformational fabric observed in surface outcrops is indistinguishable from S4 elsewhere.

GOLD MINERALIZATION

Ore-Controlling Faults: Kirkland Lake Fault (Main Break) and '04 Break

DEFINITION OF THE KIRKLAND LAKE FAULT

The Kirkland Lake fault (Main Break; Todd 1928; Thomson 1945; Thomson et al. 1950) is the main ore-controlling structure of the Kirkland Lake camp. Thomson et al. (1950) discussed the two most popular definitions of the Kirkland Lake fault that stem from different interpretations of the relationships between the Main Break and its splays (North and South veins on the Lake Shore and Wright-Hargreaves properties, and their equivalents further east). The first definition assumes the existence of a single-plane Main Break, and all splays of the Break are considered strictly subsidiary (Ward et al. 1948). Under this interpretation, the Main Break coincides with the North (No. 2) vein of the Lake Shore Mine; approximately 100 m east of Lake Shore shaft #5, the North Vein splits in a northeastern direction (050º), while the Main Break continues for about 450 m striking approximately 085-090º, where it intersects with the South vein, and coincides with the latter further east. The east-west-trending segment of the Main Break between the North and South vein is presently informally called the "Mud Break" due to intensive sericitization along it. Thomson et al. (1950) proposed an alternative concept in which the single-plane Main Break going eastward splits into more and more splays with decreasingly less displacement on each of the branches. Although one of the branches is usually stronger and accommodates more displacement than others, all splays are considered part of the same fault system. Although we agree that the second interpretation is more geologically realistic and all splays of Main Break probably constitute a single fault system along with the "parent" fault, the accompanying geologic map (Map P.3558) is based on the first (single-plane Main Break) interpretation (as compiled from Thomson 1945), primarily to reflect the well-known historical names of the most prominent veins and mineralized zones and for general simplicity of description.

CAMP-SCALE GEOMETRY

The main ore-controlling structure of the Kirkland Lake camp is the brittle to brittle-ductile Kirkland Lake fault (Main Break). It was continuously traced at surface and underground for about 4800 m, from the east limit of Kirkland Lake camp to the eastern part of Macassa Mine (e.g., Charlewood 1964). In the eastern and central parts of the camp, where mineralization extends to the surface, the ore-controlling structures were followed by underground workings from the shallowest levels to a maximum of about 2450 m depth (Charlewood 1964). Near the eastern end of the camp (Sylvanite and Toburn mines), the Main Break strikes approximately 080º; further west (the Wright-Hargreaves, Lake Shore, Teck-Hughes, Kirkland Lake Gold properties and the eastern part of the Macassa Mine), the orientation varies between 060º and 070º. The fault dips south; dip angles at the eastern-central part of the camp are generally very steep (roughly 80º to vertical at the Wright-Hargreaves and the eastern part of the Lake Shore Mine; about 70º-80º at the western part of the Lake Shore). Further west, at the Kirkland Lake Gold Mine and the eastern part of the Macassa Mine, the fault typically dips steeply (approximately 80º) to a depth of 1100-1200 m, and becomes more shallowly dipping (60º-65º) at deeper levels (Charlewood 1964). The most important splays of the Kirkland Lake fault in the east-central parts of the camp are the North and South vein structures (Thomson et al. 1950). West of the Teck-Hughes property, gold mineralization along the Main Break starts plunging about 30º-40º southwest, and near the Macassa shaft #1, the upper limit of the Main Break gold mineralization is about 900 m below surface (the 3000-foot level; Thomson et al. 1950).

Further westward, the surface continuation of the Main Break is somewhat ambiguous, because of the branching nature of the fault. In proximity to the Macassa shafts #1 and #2, at depths of 1200-1400 m, the fault splits into north and south branches, and the more persistent and better mineralized north branch connects to another fault, the '04 Break, via several minor crossover structures (e.g., R, R-2 and S breaks; Watson 1984; Watson and Kerrich 1983; Charlewood 1964). At the 4500-foot (1370 m) level of the Macassa Mine, near shaft #2, the '04 Break is approximately parallel to the Main Break, it strikes about 060º, dips 60-65º south and is located approximately 140 m north of the Main Break (Figure 26). Blocks bounded by the '04 Break and Main Break branches host important subsidiary veins (Charlewood 1964). Further west, the '04 Break becomes the main ore-controlling structure; it is also believed to be the main displacement plane in this part of the Kirkland Lake camp.

Underground (at a depth interval of about 1100-2100 m), the '04 Break was traced for approximately 1700 m, from the eastern part of the Macassa property (i.e., about 300 m southeast of Macassa shaft #1) to the Amikougami Creek fault, and a possible continuation of the structure (although unmineralized) was identified on the west side of the Amikougami Creek fault. In underground workings, the '04 Break dips steeply south (typically 65º-70º, rarely 45º-55º), and strikes northeast (055º-065º). At surface, two northeast-striking (050º-060º) near-parallel faults, 100-120 m apart, have been identified in the western part of the Macassa Mine (north of Macassa shaft #3, see Map P.3558): the north fault was previously mapped by Thomson (1945) and examined in the present project, and the south structure was identified by Macassa Mine geologists (unpublished company maps provided by Kirkland Lake Gold Inc.). On the accompanying Map P.3558, the north and south faults are interpreted as the '04 Break and Kirkland Lake fault (Main Break), respectively. Although this interpretation may be not entirely correct (correlation of surface features with structures at depth >1000 m could be uncertain), most probably both faults are related to the Kirkland Lake fault system. Dikes and elongate stocks of the mafic syenite and syenite porphyry are spatially associated with the two faults. In surface exposures north of Macassa shaft #3, the main slip of the northern fault coincides with a contact of a narrow (5 m) strongly deformed, foliated mafic syenite dike.

Surface mapping of this project reveals that there may be another fault, located roughly 350-400 m north of Macassa shaft #3 and striking approximately 050-055º. A rather abrupt decrease in intensity of S4 foliation (north – foliated, south – unfoliated or weakly foliated) in Timiskaming conglomerates was observed north of Macassa shaft #3 (outcrops along Macassa ore haul road) and west of Macassa shaft #2 (outcrops along the powerline). This change in deformation strength may be due to the existence of a fault separating blocks with different strain intensity (Figure 27).

SURFACE AND UNDERGROUND EXPOSURES

The Kirkland Lake fault is exposed underground at the Macassa Mine (eastern sections), and at surface on the Wright-Hargreaves, Lake Shore, and Teck-Hughes properties. Underground, unmineralized portions of the fault were observed at the 4500-foot level of the Macassa Mine, in proximity to shaft #2. At this location, the fault strikes 060º-070º, dips approximately 70º south and consists of a single 7-10 cm wide chlorite gouge band, and, less commonly, of a wider (30-50 cm) zone of breccia and branching chloritic slips. Veins of late, barren translucent quartz, with white and pink carbonate, and rare chlorite rosettes, are hosted by the fault (Photo 36). Along the fault plane, the rocks are typically carbonatized, and deformed into fine-grained cataclasite. The chloritic surface of the main slip plane contains gentle striations (orientation shown in Figure 28). The most common orientations are a) steep (raking approximately 60-90º, both east and west) and b) plunging shallowly to the west (5-30º). Shallowly west-plunging striations are documented to overprint the steeply plunging striations.

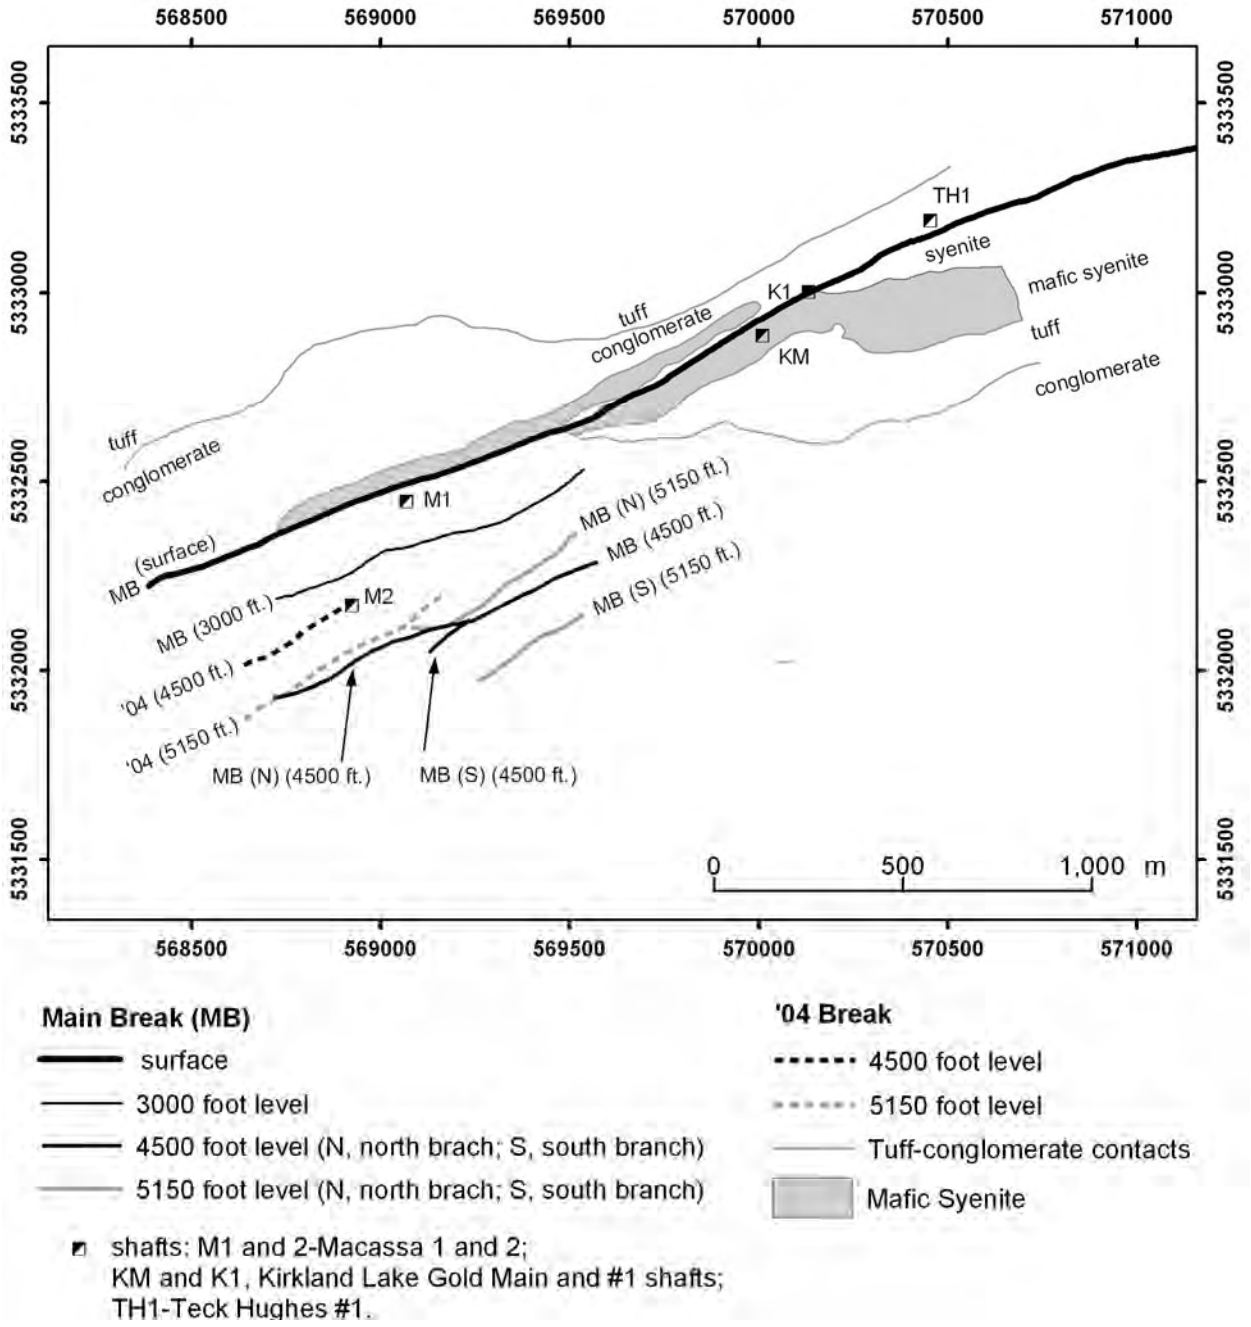

Figure 26. Subsurface position of the Main Break and ’04 Break in proximity to Macassa shafts #1 and #2. (Also shown are surface geological markers: tuff-conglomerate contact and mafic syenite intrusion). The Main Break splits into north and south branches; east of Macassa shaft#1, the north branch of the Main Break reverses dip to the north. At the 4500-foot level, the ’04 Break is located about 140 m north of the Main Break (north branch). Further west, the ’04 Break becomes the main ore-controlling structure. Data from Thomson et al. (1950) and Charlewood (1964).

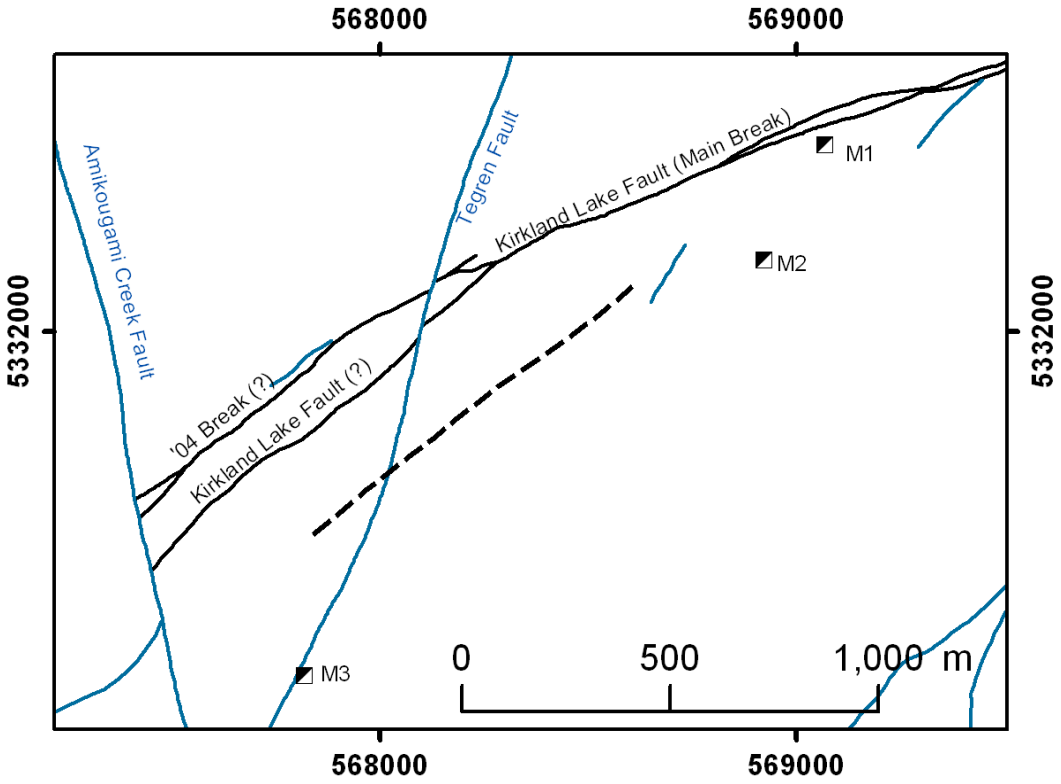

Figure 27. Possible fault location south of the Main Break (thick dashed line). Based on abrupt decrease in S4 foliation intensity in Timiskaming conglomerates (from north to south), observed in outcrops along the Macassa ore haulage road (north of shaft #3) and along the powerline (west of shaft #2). M1,2, and 3- Macassa shafts #1, #2, and #3.

Photo 36. Main slip plane of the Kirkland Lake fault (Main Break) in the back of the drift, 4500-foot level, Macassa Mine. The Main Break hosts post-ore, barren quartz-carbonate-chlorite vein. Pencil is 15 cm long.

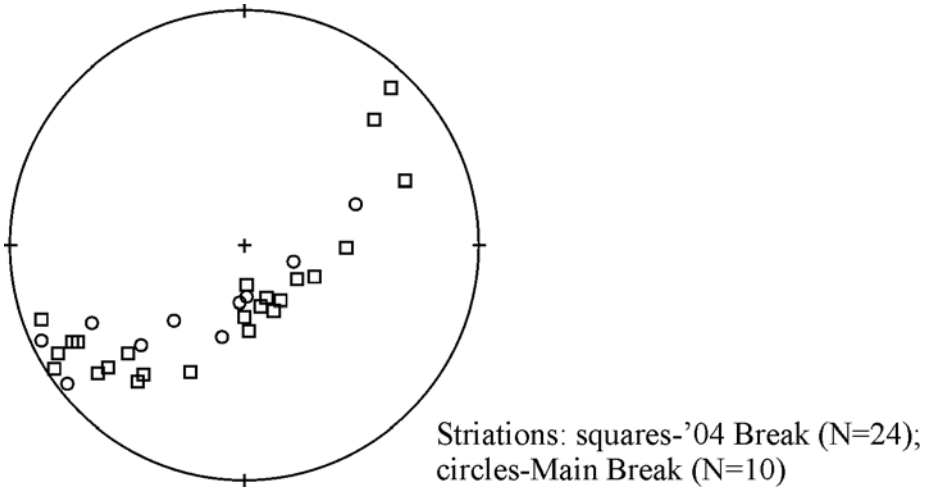

Figure 28. Orientation of striations on chloritic slip surfaces of the Main Break and '04 Break. All data from Macassa underground workings.

At surface, the Main Break is best exposed on the Lake Shore property, east of former shaft #5. It consists of several northeast-striking (060-075), south-dipping (75-80º), 10-25 cm wide deformation bands, characterized by strong sericitic alteration. These bands show an internal foliation oriented oblique to their boundaries, both in plan and cross-section view. In plan view, the foliation is oriented at 15-20º counterclockwise to the boundaries of the bands; in cross-section view, the foliation dips steeper (or even shows vertical orientation or steep north dips) than the deformation bands (Photo 37). The orientation of the foliation suggests reverse-dextral (south side up and to the west) slip along the Main Break.

Another surface exposure of the Main Break is the flooded small open pit, exposing the "Mud Break", i.e., the east-west-trending segment of the Kirkland Lake fault between the North and South veins near the west border of the former Wright-Hargreaves property (Figure 29). Observations in 2002, prior to mining operations, show that this segment of the Main Break is a 3-4 m wide high-strain zone. The zone consists largely of sericite-rich highly foliated syenite porphyry (Photo 38A). The sericite alteration is associated with small quartz veinlets and is symmetrically distributed in the wall-rock selvages (Photo 38B). The foliation trends east-northeast, parallel to the overall orientation of the Mud Break segment and is syn- to post-sericite alteration. The sericite is oriented parallel to or has been transposed by the foliation (Photo 38C). A roughly 20 m wide zone of low-grade (Au ≤ 3-4 g/t) mineralization is associated with the Mud Break. Mineralization comprises a weak quartz stockwork and a strong hydrothermal replacement characterized by silicification and sericite, with 2-10% disseminated pyrite.

The '04 Break was observed underground at the 3825, 4250, 4500, 4750, and 4900-foot levels of the Macassa Mine. It is similar in orientation (northeast strike (055º-065º), south dip (60º-70º)) to the Main Break, and is defined by similar narrow (2-10 cm) single or branching chloritic bands and locally wider (20 cm to 1 m) breccia zones, as in the Main Break. The discrete fault slip surfaces are commonly accompanied by wider (0.5-2.5 m) envelopes of carbonatized fine-grained cataclasite traditionally called "mylonite" in mine terminology. The cataclasite shows a banded texture defined by reddish-brown lenses and discontinuous bands (1-3 cm wide), separated by a darker chloritized matrix, or has a more uniform, greyish light brown color. Typically, cataclasite is aphanitic, however, 1-2 mm feldspar fragments are

recognizable in places. Thomson et al. (1950, p.100) described the petrography of these fault rocks, characterizing them as carbonate-rich cataclastic microbreccias consisting primarily of fragmented feldspars and secondary carbonate. Cataclasite bands are commonly bounded by sharp slip surfaces. Foliation in cataclastic bands, if present, is in most cases parallel to the fault boundaries. On the western face of stope 4528 MCF, weakly developed foliation defined by alignment of breccia clasts and diffuse compositional banding is oriented steeper (80º-85º south) than boundaries of the cataclastic band (approximately 55º-60º south), which is compatible with reverse sense of shear (Photo 39). In addition to the oblique foliation observed in stope 4528 MCF, the main ’04 Break slip is in places (e.g., stope 4940) accompanied by more shallowly dipping fractures, oriented at about 20º to the slip plane (in cross section view). These can be interpreted as synthetic Riedel fractures compatible with reverse slip. Gentle striations on chloritic slip surfaces of the ’04 Break are either steep or moderately to shallowly inclined to the west. East-plunging striations are relatively rare (Figure 28). As discussed below, the striations on chloritic slip surfaces probably record post-mineralization movements.

Other, subsidiary, ore-controlling structures in the Macassa Mine include the South Break, ‘05 Break, and No. 6 Break (Still 2001). Of these structures, only the No. 6 Break was observed in this study. The No. 6 Break apparently splays from the ’04 Break above the 4250-foot level. It strikes about 070º, dips 40º-55º to the south, and diverges from the ’04 Break with depth (Still 2001). The wedge-shaped block between the 4250-foot and 4500-foot levels confined by the ’04 Break and No. 6 Break is the host of several economically important ore zones (Still 2001). The No. 6 break was briefly examined in stope 4225 (above the 4250 level), where it occurs as a narrow (3-5 cm) chloritic fault separating augite syenite (footwall) and tuff (hanging wall).

Plunge of Gold Mineralization

One of the most notable features of the Kirkland Lake gold camp is the westerly plunge of the Main Break mineralization. It begins approximately from the western boundary of the Teck-Hughes property (close to Kirkland Lake Gold shaft #1) and continues to the Macassa Mine 3000-foot level, between shafts #1 and #2 (Figure 30). Along this plunging interval, the upper boundary of mineralization approximately coincides with the top of the pipe-like syenite body in the hanging wall of the Main Break (e.g., Charlewood 1964). From the 3000-foot level of the Macassa Mine (between shafts 1 and 2), the upper limit of the ore drops steeply to the 4375-foot level, and the ’04 Break becomes the main ore-controlling structure at deeper levels and further west (Charlewood 1964). West of Macassa shaft #2, mineralization along the ’04 Break does not show a single, clearly defined, plunge. At present, ore hosted by the ’04 Break is actively mined at the 3825-foot level at the western part of the Macassa Mine and there are no clear indications for upper limits of mineralization.

The westerly plunge of mineralization between the Teck-Hughes Mine and the eastern part of Macassa shafts #1 and #2 corresponds to the segment of the Main Break that is oriented 20º-30º counterclockwise with respect to the strike of stratified units (tuffs and conglomerates) and to the western contact of larger, near concordant, part of the mafic syenite body (Figure 31). The general plunge of Main Break mineralization from surface to the 3000-foot level at Macassa is approximately parallel to the calculated intersection line between the Main Break and the tuff-conglomerate contact south of the Main Break (Figures 31 and 32). The plunge of the westernmost tip of an irregular pipe-like syenite body in the hanging wall of the Main Break between surface and the 3000-foot level of the Macassa Mine has approximately the same orientation. The intersection of the Main Break and the tuff-conglomerate contact north of the Break is oriented similarly. The end of the plunge at the 3000-foot level of the Macassa Mine corresponds to the area where the general trend of stratified units changes from east-west to northeast, i.e., becoming approximately parallel to the Main Break.

Photo 37. Surface exposure of the Main Break east of the former Lake Shore shaft #5 (top, plan view, west is on the right-hand side; bottom, cross-section view facing west). At this location, the Main Break comprises several sericitic deformation bands; photographed is one of these bands. Oblique (in plan and cross-section view) orientation of internal foliation (dashed lines) with respect to the boundaries of the band (solid lines) implies oblique reverse–dextral (south-side up and to the west) sense of movement.

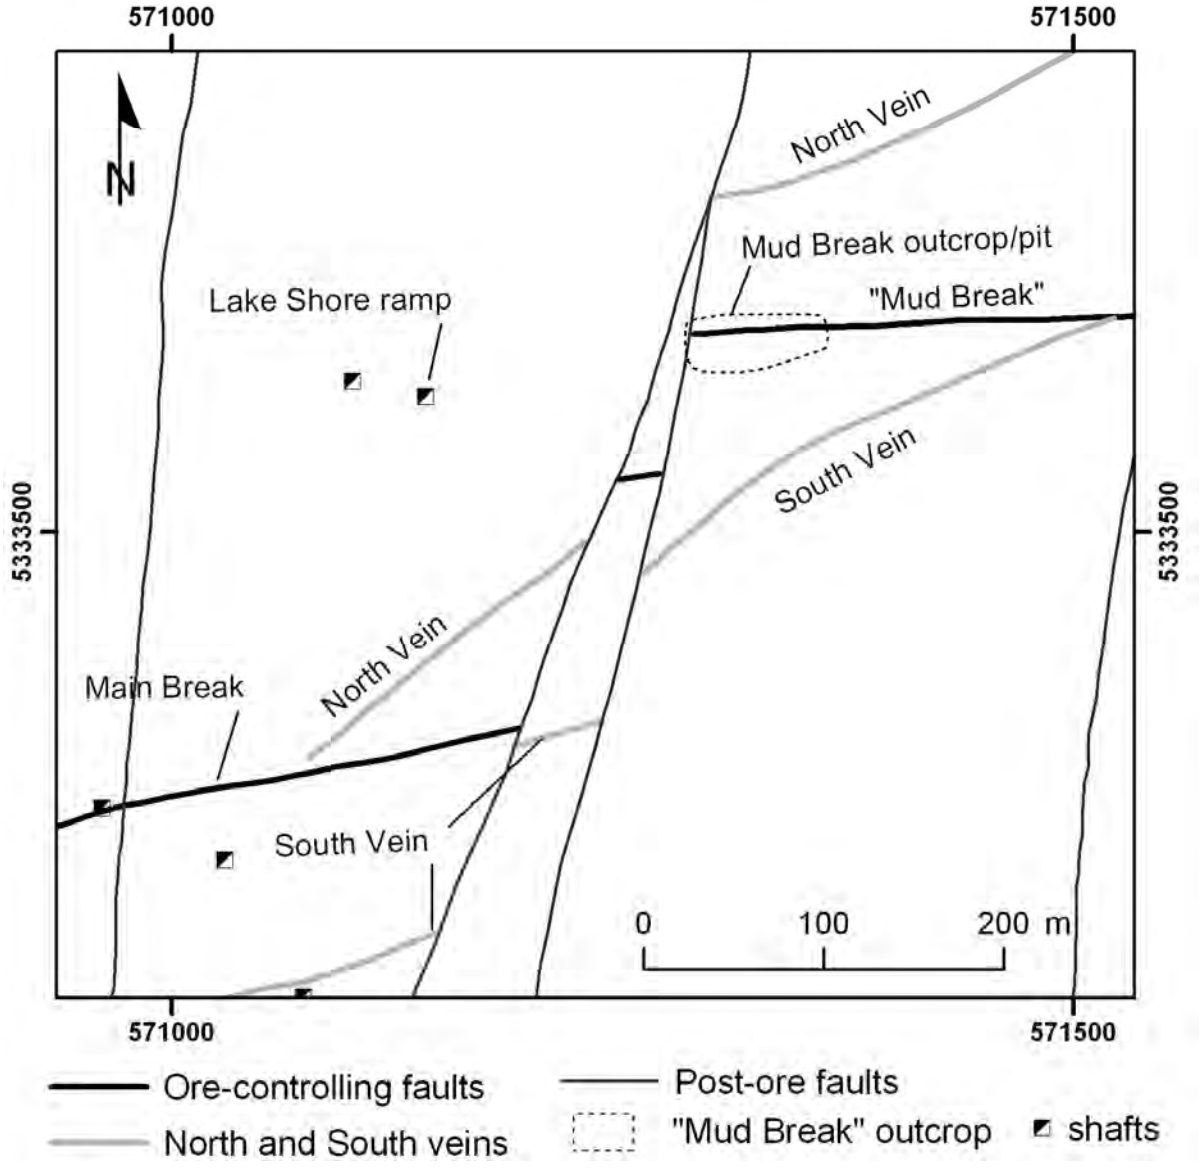

Figure 29. Schematic showing the location of the “Mud Break”.

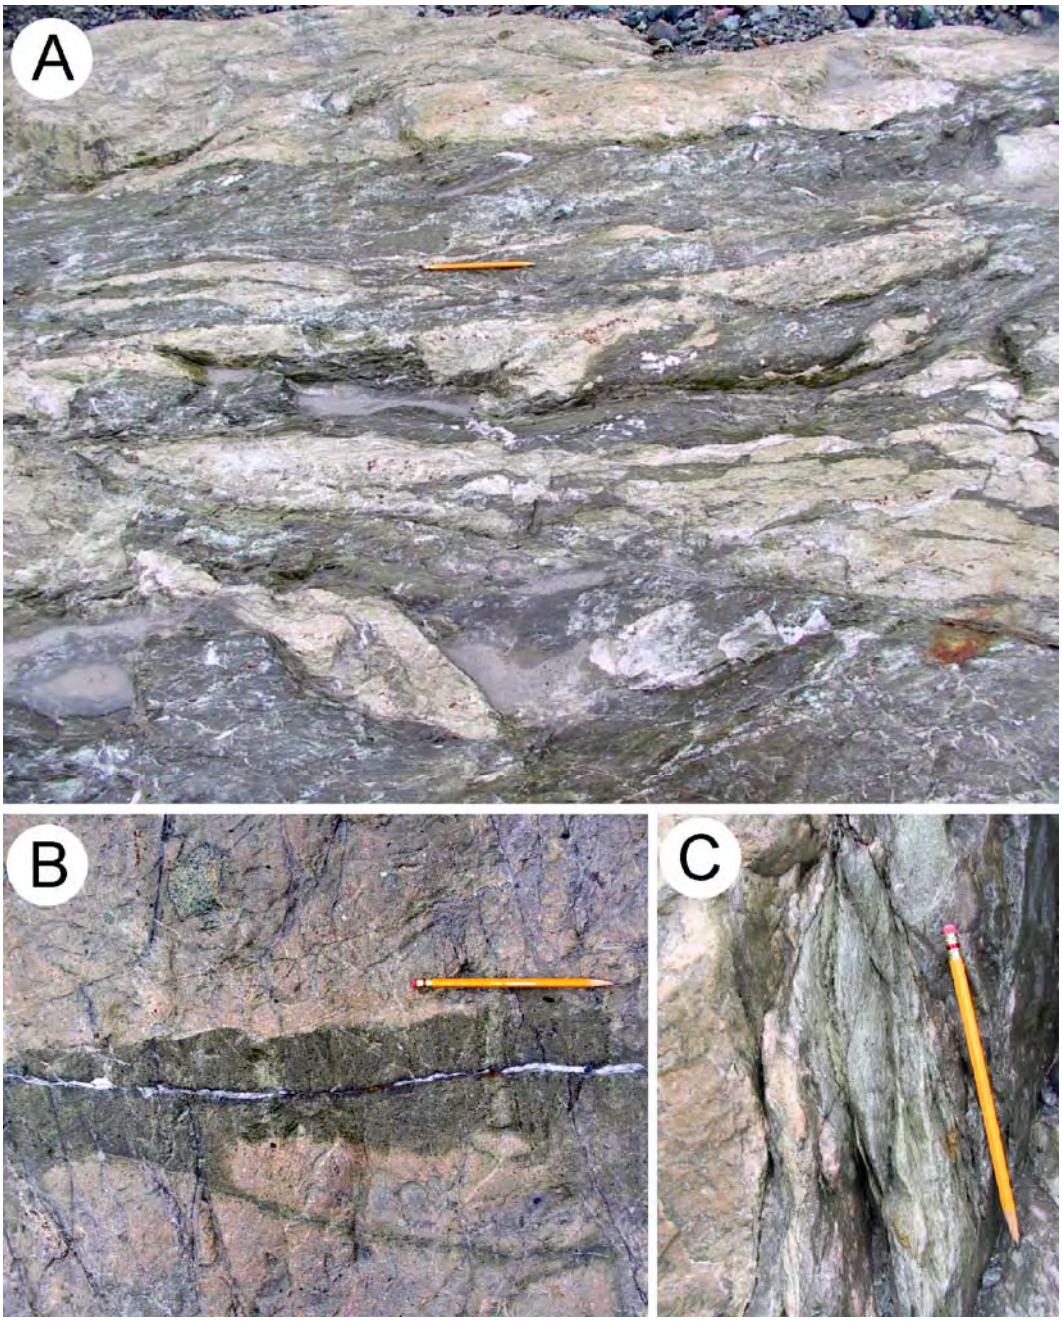

Photo 38. Surface exposure of the "Mud Break" (pencil, approximately 15 cm, for scale). A) General view of the "Mud Break": foliation in strongly sericitized syenite porphyry. B) Sericitization halo (dark) around a thin quartz veinlet. C) Cross-section view of a foliated sericite-rich band.

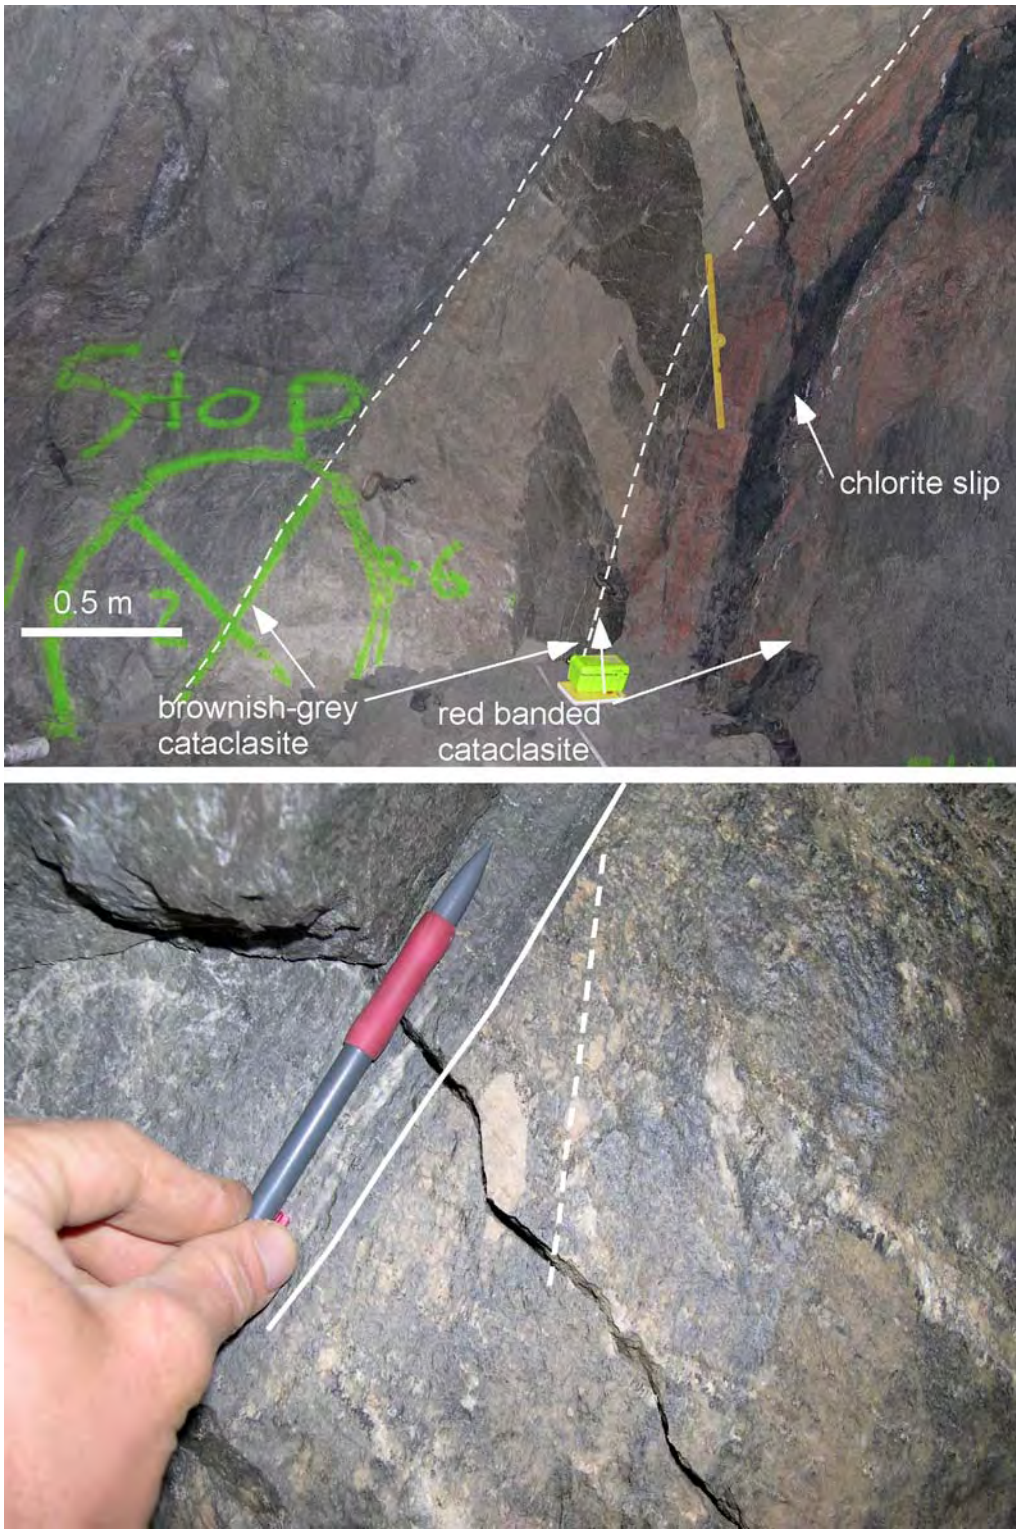

Photo 39. Underground exposure of the '04 Break in stope 4528 MCF, Macassa Mine. Cross-section view facing west. Top, general view towards west end of the stope. Main chloritic slip of the break is flanked from the south by bands of red and brownish-grey cataclasite. Bottom, a close up view of the southern contact of the brownish grey cataclasite band. Weakly developed internal foliation (dashed line), defined by clast alignment, dips steeper than the contact of the band (solid line), which is compatible with reverse (south over north) sense of shear.

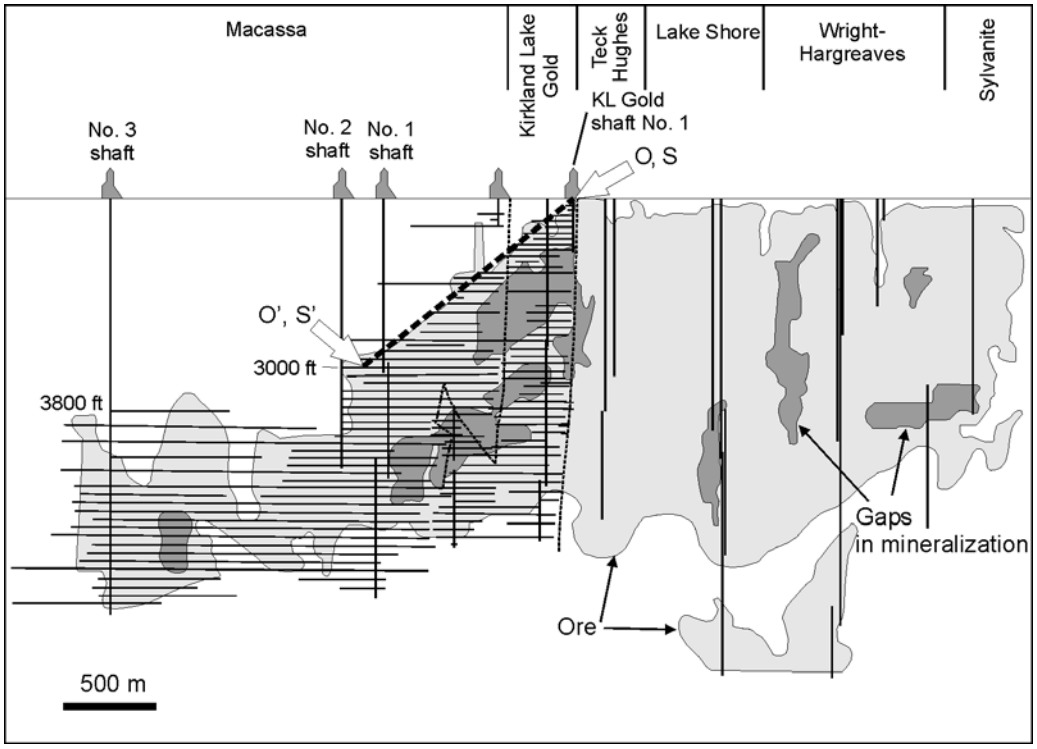

Figure 30. Schematic longitudinal section of the Kirkland Lake camp. Modified from Still (2001) and Ridler (2001). Arrows depict position of points O, S, O', and S' from Figure 31.

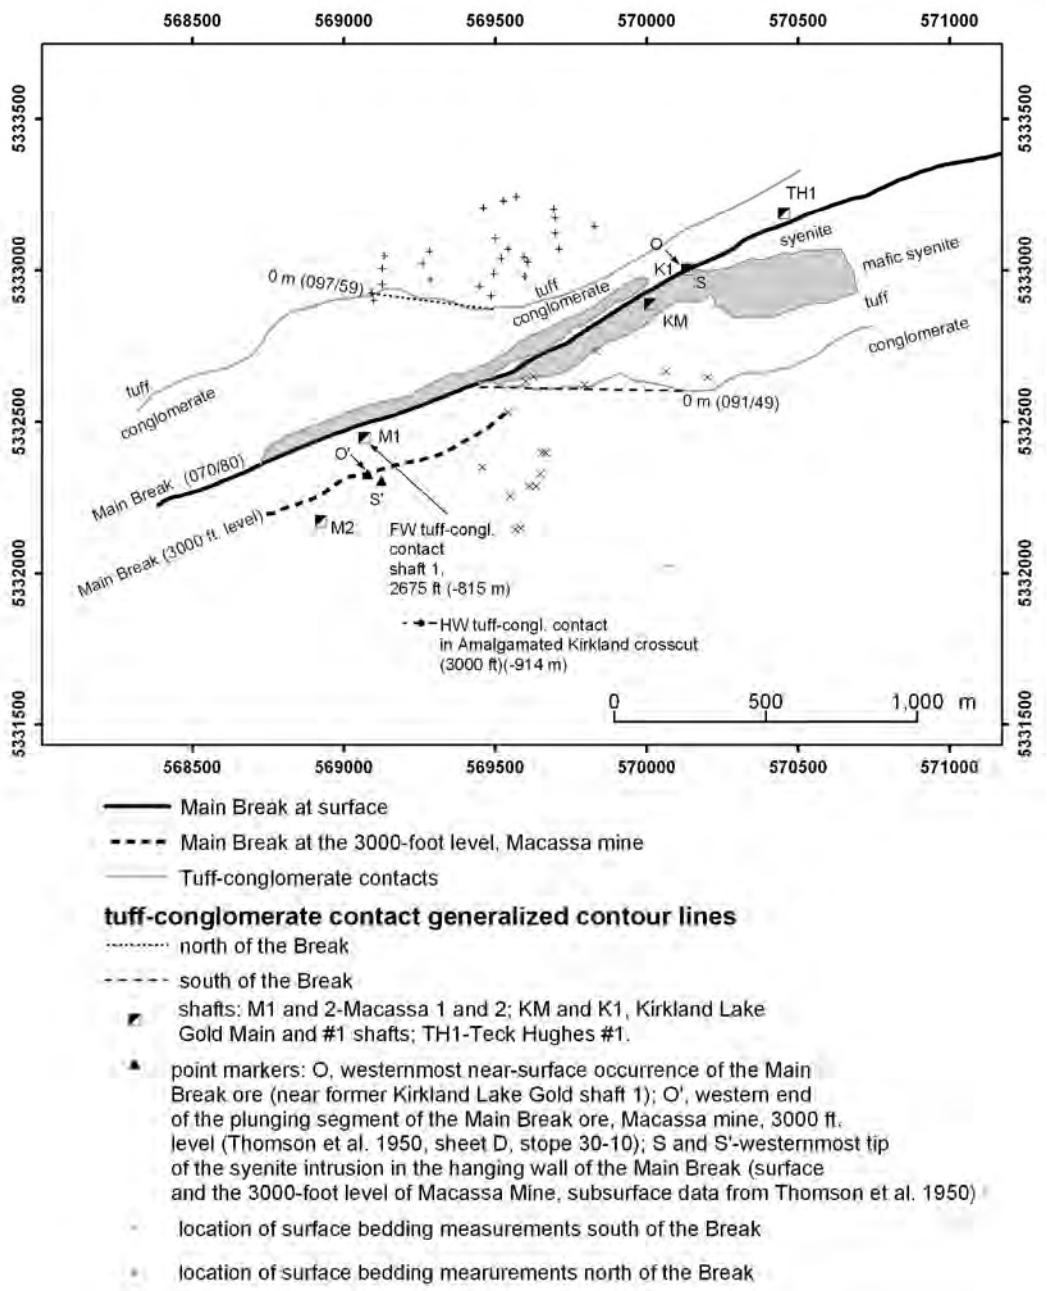

Figure 31. Diagram explaining elements shown in Figure 32. Main Break strikes 070º and dips 80º between surface and the 3000-foot level of Macassa Mine. Straight dotted (north of the Break) and dashed (south of the Break) lines are generalized contour lines of the tuff-conglomerate contact (actual contact is shown as a solid grey line). Orientation of the contact is 097/59 north of the Break and 091/49 south of the Break. Dip angles are calculated based on intersections in Macassa shaft #1 (north of the Main Break, 2675-foot level, data from Charlewood 1964) and in Macassa Amalgamated Kirkland crosscut at the 3000-foot level (data from Lackey 1990), assuming planar geometry. O and O' (triangular symbol) depict the westernmost surface exposure of the Main Break ore (near the former Kirkland Lake Gold shaft #1) and the western end of the plunging segment of the Main Break ore on the 3000-foot level at the Macassa (Thomson et al. 1950, sheet D, stope 30-10). S and S' correspond to positions of the westernmost tip of the pipe-like syenite body in the hanging wall of the Main Break, respectively, at surface and at the 3000-foot level of the Macassa Mine. For legibility, the syenite porphyry intrusions are not shown (see Map P.3558 for details).

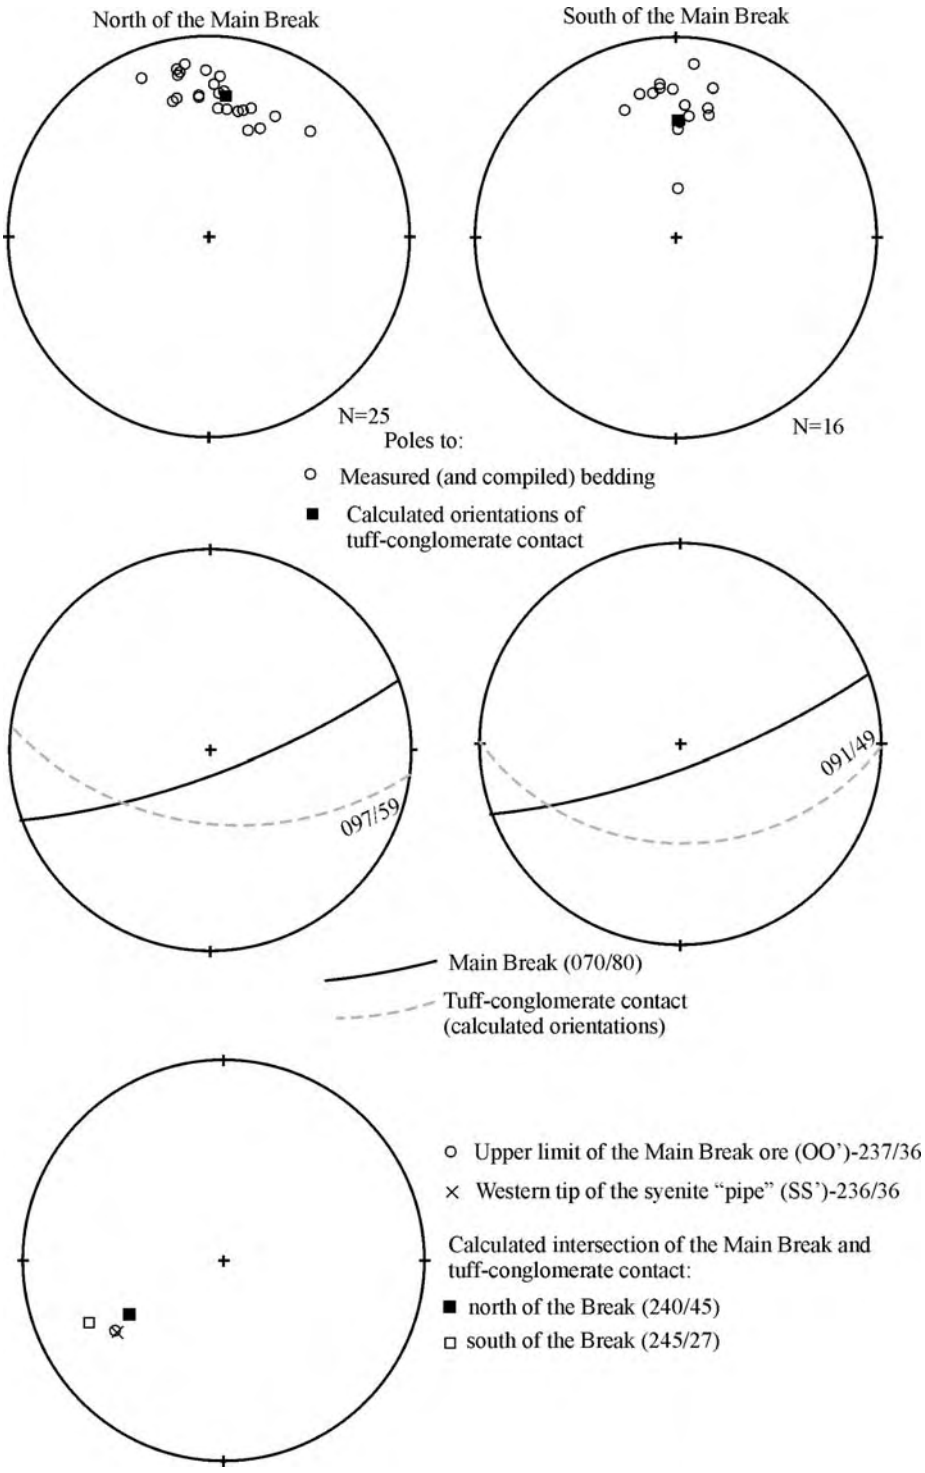

Figure 32. Stereonets comparing ore plunge to other structural elements. The upper row compares calculated orientations of the tuff-conglomerate contact with actual bedding measurements, north and south of the Main Break. The middle row shows angular relationships of the Main Break (between surface and the 3000-foot level of the Macassa Mine) and the tuff-conglomerate contact (north and south of the Break). The lowermost net depicts trends and plunges of the western limit of the Main Break ore (OO' line of Figure 31), of the westernmost tip of the pipe-like syenite body (SS' line of Figure 31), and of calculated intersections between the Main Break and tuff-conglomerate contact (north and south of the Break).

Gold-Bearing Quartz Veins

GEOMETRY AND INTERNAL FEATURES

Auriferous quartz veins were observed mainly underground, at the 3825, 4250, 4500, 4750, and 4900-foot levels of the Macassa Mine, where they are hosted by mafic (augite) syenite, tuff and syenite porphyry. Principal types of gold mineralization in Macassa include "break ore"(gold-bearing quartz veins hosted by or localized in the immediate proximity to the Main Break and the '04 Break), footwall and hanging wall veins, and breccia ore (Still 2001). From these ore types, break ore (break veins) and hanging wall veins were examined in the present project. Breccia ore (i.e., ore confined between major faults, consisting of altered, silicified and strongly fractured rocks, with pods and lenses of quartz; Watson and Kerrich 1983; Still 2001) was not accessible at the time of this study. In addition to veins in the Macassa Mine, observations were made on the Teck-Hughes #1 vein, and veins hosted by the Main Break (east of the former Lake Shore shaft #5, and the Discovery ouctcop vein on the former Wright-Hargreaves property). Due to clear association with major steeply dipping fault structures, these three veins can be classified as "break ore" under Macassa Mine nomenclature.

Veins localized along the '04 break at the Macassa Mine (e.g., stopes 4247, 4940, 3826, 3829) generally dip 60º-80º south (near parallel to the host structure) with local shallower and steeper dips. Veins may be localized along the main slip of the '04 Break or along subsidiary fractures in close proximity to the main slip. Typically, these are clear-cut, planar, roughly 15-50 cm thick veins consisting largely of milky white quartz (see further discussions of vein textures and quartz types). Less common are irregular and discontinuous pockets of grey to dark grey quartz along the '04 Break (stopes 4940 and 4517, Photo 40). Most stoped "break ore" bodies consist of several veins, some of which may be oriented obliquely (up to 30-40º) to the break. Some of these oblique veins terminate abruptly against the main chlorite slip (e.g., stope 3826), probably indicating post-ore movement along the '04 Break. Contacts of break-associated veins with wall rocks are sharp or, less commonly, gradational, through sheeted veinlet zones.

A gold-bearing vein hosted by the Main Break is exposed on the Discovery outcrop (the former Wright-Hargreaves property). Along the north contact of the vein (over about 0.5 m), the host syenite porphyry is distinctly foliated (Photo 41). The foliation is sub-parallel to the vein contact and defines a strain gradient towards the vein. The north margin of the vein is marked by a roughly 5-7 cm wide band of cataclasized quartz (Photo 42). Similar cataclasite is present in the Teck-Hughes #1 vein that is hosted by a subsidiary splay of the Main Break.

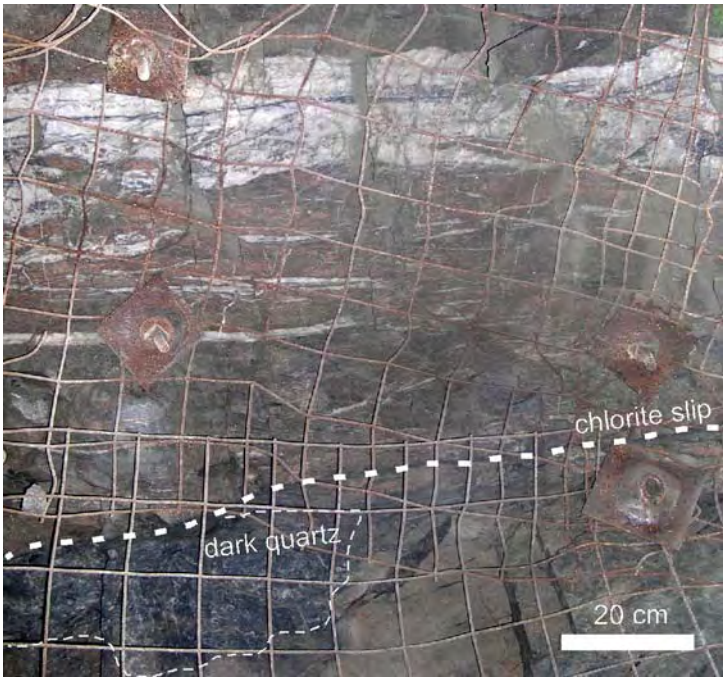

Photo 40. Gold-bearing quartz veins associated with the ’04 Break; back of stope 4940, Macassa Mine, west is on the left-hand side. Planar vein 0.5-1 m south of the main chloritic slip of the ’04 Break and irregular pod of dark quartz along the slip. Both are gold-bearing (samples 4940-1 and 4940-3, listed in Appendix A are, respectively, from the planar vein and the irregular quartz pod).

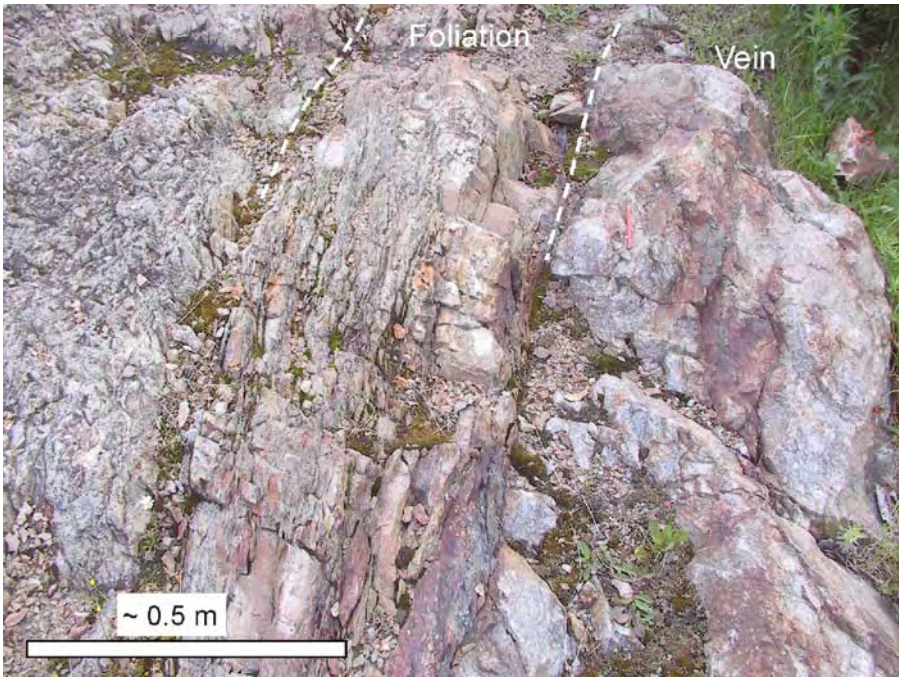

Photo 41. Foliation north of a gold-bearing vein hosted by the Main Break (Discovery outcrop, facing east).

Photo 42. Cataclastic band (C) along the margin of the gold-bearing vein (Discovery outcrop, facing north). Pen magnet (approximately 12 cm) for scale.

The break-associated auriferous veins are characterized by massive, banded and breccia textures, which typically alternate along and across the strike of a single vein. Massive portions of veins consist of uniform white quartz filling. Banded to laminated texture is defined by irregular bands of darker quartz, sharp slip surfaces coated with fine molybdenite and graphite (?), and 0.5 to 3 cm thick slivers of host rocks oriented parallel to vein walls. Also characteristic is the presence of stylolites approximately parallel to the vein boundaries (Photos 43 and 44), with approximately horizontal, northwest-southeast-oriented teeth (cones). Length of stylolite teeth varies from millimetres to 1-1.5 cm. Stylolites are marked by dark films of fine molybdenite-graphite material and locally (e.g., stopes 4940, 3829) contain fine gold and telluride grains, along with pyrite and chalcopyrite. Slabs and slivers of host rocks enclosed in vein material are either weakly foliated or completely unfoliated. In a sample from Main Break-hosted vein from the Lake Shore property (east of former Lake Shore shaft 5), mineralized quartz encloses foliated streaks of hydrothermal sericite. Slivers of chlorite seams that presently mark the main slip surface of the ’04 Break and subsidiary faults in Macassa have not been seen enclosed by the gold-bearing quartz veins. Breccia veins and vein intervals consist of angular, unrotated clasts of host rocks cemented by white quartz. In some veins, rock fragments are surrounded by a thin (0.5-1 mm) dark rim of fine molybdenite-graphite aggregate. Most break-associated gold-bearing veins underwent weak to strong fracturing and, locally, cataclasis. Cataclastic breccia of white vein quartz cemented by dark grey gangue material occurs in the Main Break-hosted vein on the Discovery outcrop and in the Teck-Hughes #1 vein. In the Teck-Hughes #1 vein, this dark grey cement consists of fine-grained quartz-sericite aggregate (sericite > quartz) with finely dispersed opaque matter (possibly graphite and/or molybdenite). Gold and tellurides are present both in quartz fragments and (mostly) in the dark quartz-sericite matrix indicating that the brecciation overlapped with mineralization (Photo 45). In stope 4938 at the Macassa Mine, fractured gold-bearing quartz is cemented by a barren, post-ore quartz-chlorite aggregate, reflecting post-mineralization movements along the ’04 Break.

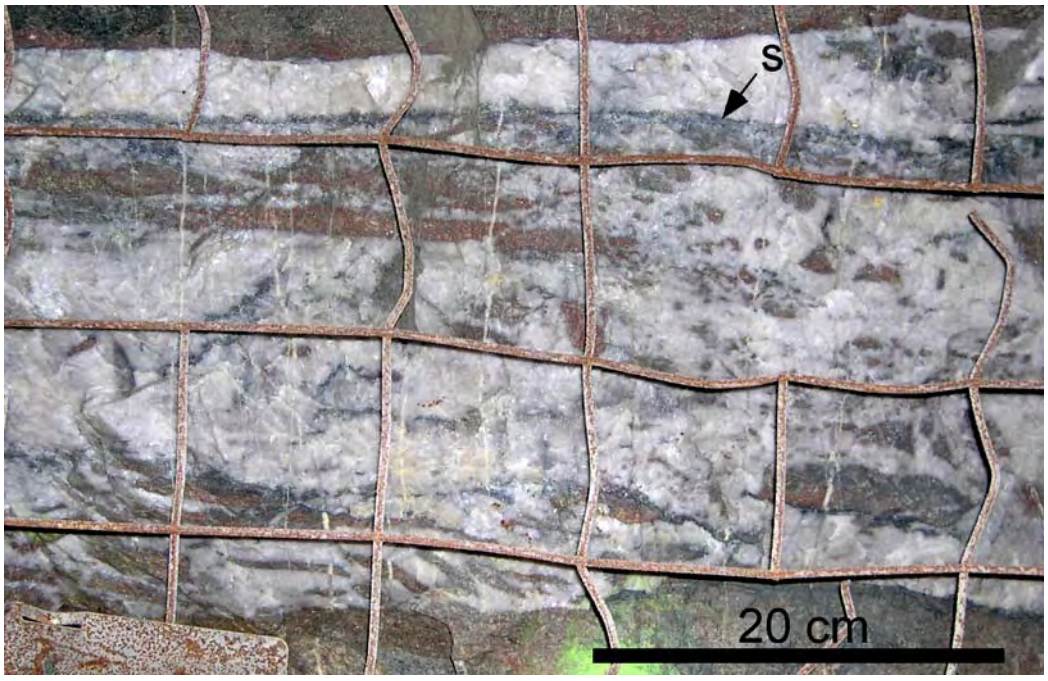

Photo 43. Typical textural appearance of a steeply (roughly 70º) dipping vein associated with the ’04 Break (stope 4940, Macassa Mine). Slabs and angular fragments of host rocks are cemented by quartz; dark stylolite surface (marked “s”) is parallel to vein walls.

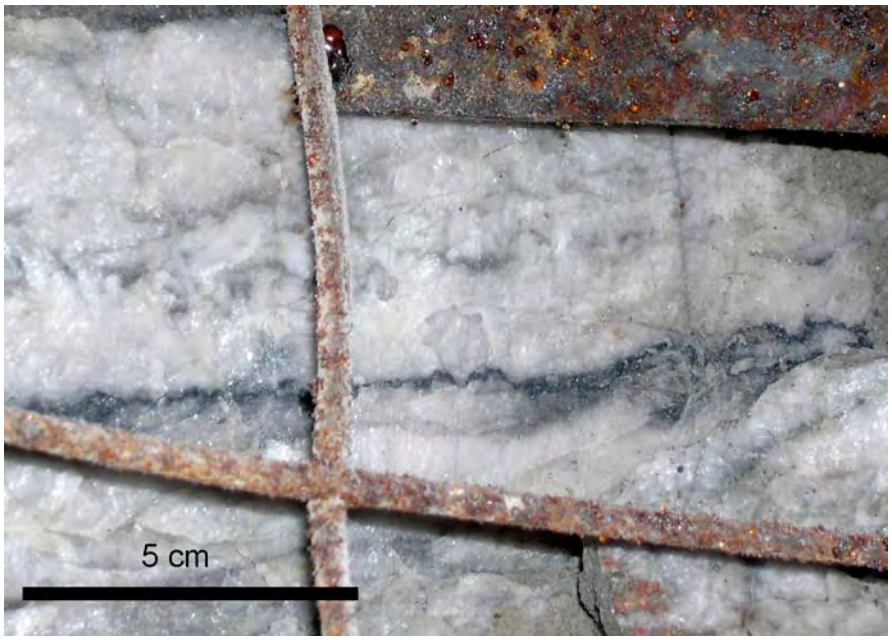

Photo 44. Close-up view of a stylolite in a break-associated vein (’04 Break, stope 4940, Macassa Mine).

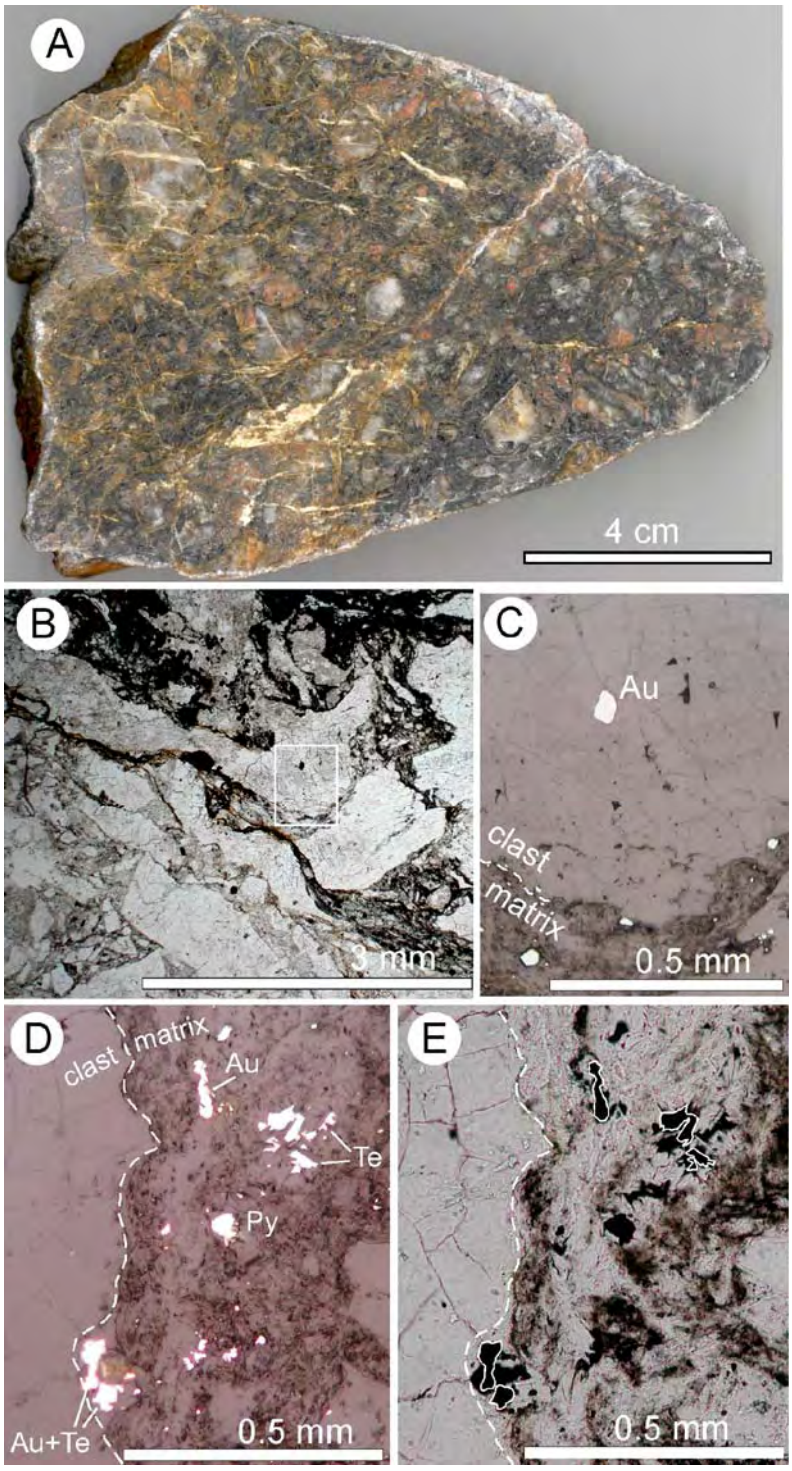

Photo 45. Cataclasized quartz from Teck-Hughes #1 vein. A) polished slab: angular fragments of quartz (light colored) and, more rare, of host syenite porphyry are cemented by dark grey quartz-sericite aggregate (sericite >50%). B-E) photomicrographs (B and E, transmitted plane-polarized light; C and D, reflected light). Gold (Au) and tellurides (Te) (0.01-0.02 mm) occur in quartz clasts (C) and (more frequently) in sericite-rich cementing aggregate (D and E), indicating that cataclasis overlapped with mineralization. Dark coloration of the cementing aggregate is largely due to the presence of very fine opaque, non-reflective particles, possibly molybdenite and graphite (or carbon). Geochemical data for this sample (sample 1254-2) are listed in Appendix A. In surface exposure of the #1 vein, dark cataclasized quartz represented by this sample is volumetrically subordinate to white quartz with wall rock clasts.

Hanging-wall veins exhibit a variety of orientations: from shallow (10-35º) to steep (60º-70º) south dipping, and some veins in a wedge-shaped block between the 04' and No. 6 breaks dip steeply (60-70º) north. Thickness of individual veins varies from 5-7 cm to 0.5-1.0 m. The steeply north- and south-dipping hanging-wall veins are associated with minor subsidiary fault structures and are overall similar to break-related veins. In fact, for veins located close (e.g., within about 5 m) to the '04 Break, classification into "break" or "hanging wall" category is arbitrary.

Shallowly south-dipping (10-40º) hanging-wall veins tend to become steeper towards the north, as they converge with the '04 Break (Still 2001; M. Sutton, Kirkland Lake Gold Inc., personal communication, 2004). The flatter portions of these veins also tend to have higher gold grade (Still 2001). Details of localization of individual veins vary. Moderately to shallowly dipping veins hosted by tuffs are generally bedding-parallel (e.g., stopes 4713, 4512, 5030). In stope 4744, a gently (about 30º) south-dipping vein is hosted by a mafic syenite sill intruding tuffs. The vein is located close to the contact of the sill, and is approximately parallel to it. The largest of the observed shallowly to moderately dipping veins, 4206-S3, strikes 055º to 100º and dips about 30-35º south; it is hosted entirely by mafic syenite, and is spatially associated with a small fault that dips 30º to 60º south (Photo 46). The fault (and probably the vein) appears to become steeper towards the south (near the southern wall of the stope).

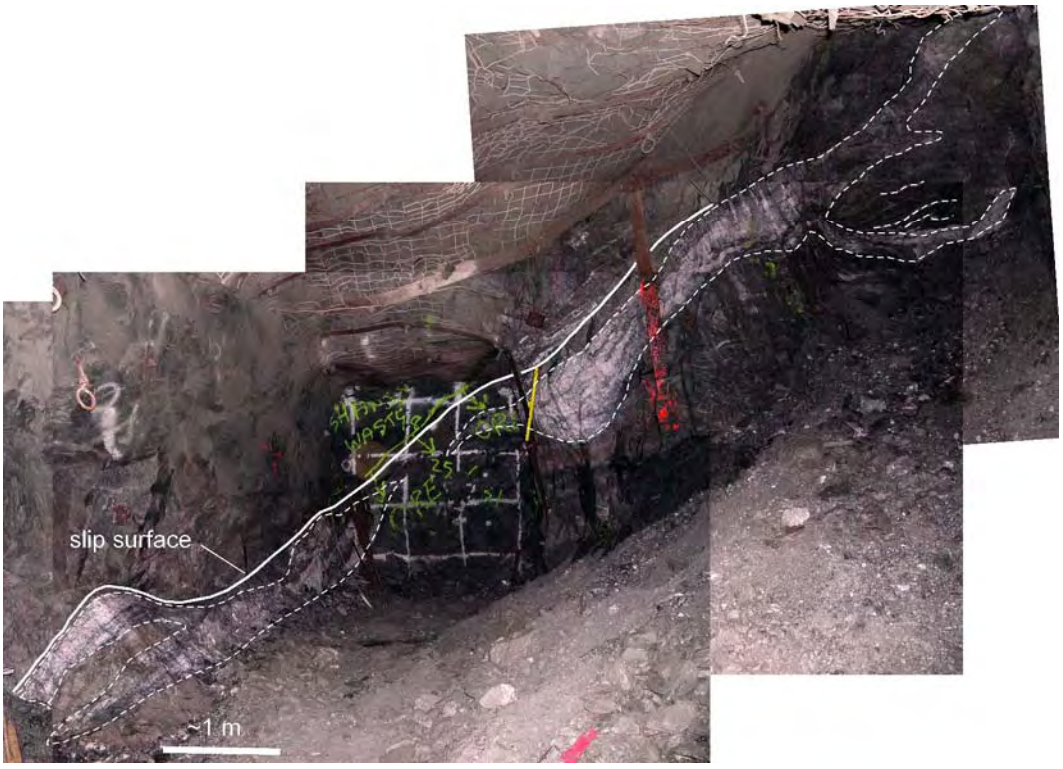

Photo 46. Vein 4206-S3 (Macassa Mine). Cross-section view facing approximately west. Vein is spatially associated with a small fault that typically dips about 30-40º south but steepens to 55-60º (S) near the southern wall. The vein is hosted by mafic syenite.

It should be noted that even veins that are approximately concordant to bedding or lithological contacts tend to be spatially associated with minor faults or slips, i.e., it is more appropriate to consider these veins as controlled by tectonically re-activated surfaces. For example, in stope 5030, a vein striking about 115-120º and dipping about 20º (southwest) is hosted by tuffs and is associated with two sharp bedding-parallel slips. A graphite-molybdenite-coated slip surface in a footwall of the vein contains approximately dip-parallel striations. The vein consists of concordant (i.e., bedding- and slip-parallel) banded or breccia intervals and discordant breccia pockets (Photo 47). The geometry of the latter can be interpreted as dilational jogs formed during reverse (southwest over northeast) movements along bedding-parallel slips.

Texturally, steeply and shallowly dipping hanging-wall veins are similar to steep, break-associated veins. Massive, banded and breccia textures alternate along and across strike of individual veins. Boundary-parallel sharp stylolites were observed both in steeply (roughly 60º, stope 4229-5) and more shallowly (30-45º, stope 4512) south-dipping hanging wall veins. In a moderately dipping (30-45º) vein in stope 4512, stylolite teeth are oriented near horizontal, at about 45º to vein boundaries and stylolite planes. Perhaps slightly unusual is a banded texture of vein 4206-S3, where bands of white and dark quartz, and breccia layers make up a crudely layered crustiform-like banding (Photo 48). Similar to break-associated veins, shallowly and steeply dipping hanging-wall veins are commonly fractured. In some gold-rich segments of the 4206-S3 vein gold and telluride mineralization is associated with late fracture filling along irregular network (Photo 49A,B).

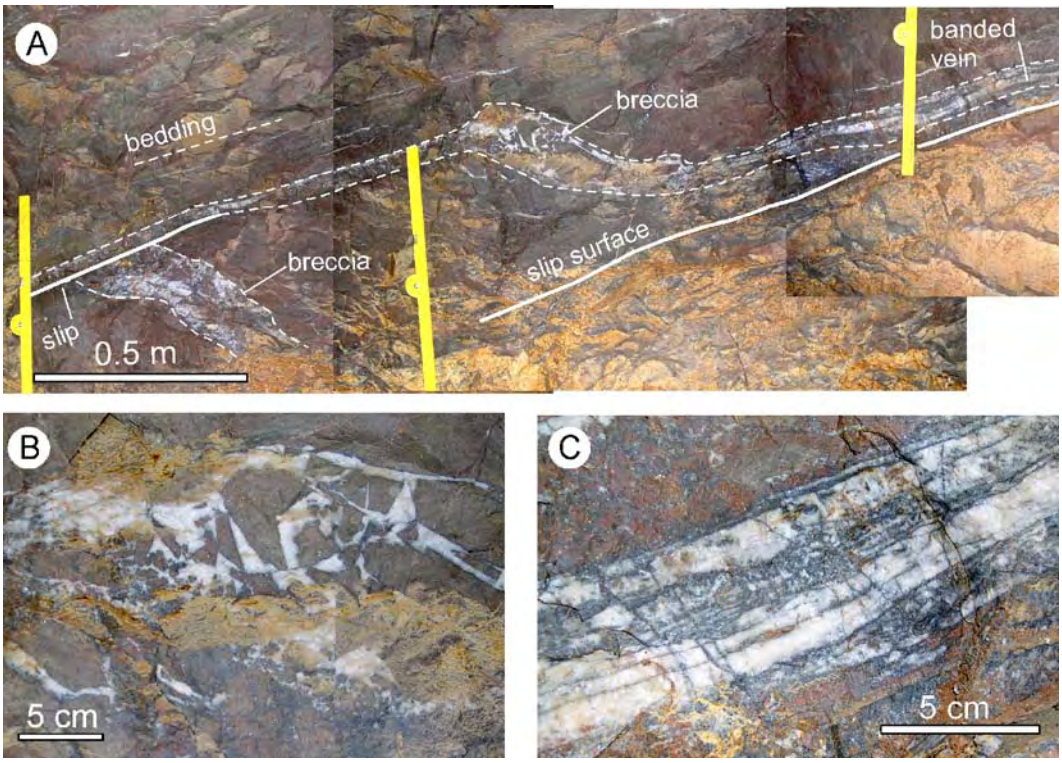

Photo 47. Bedding-parallel vein in tuffs (stope 5030, Macassa Mine, cross-section view, west-southwest is on the left-hand side). Breccia pockets discordant to bedding may have formed as dilational jogs during reverse motion along slip planes. B) close-up view of a breccia interval: angular wall rock clasts cemented by white quartz. C) banded texture defined by dark fractures and bands.

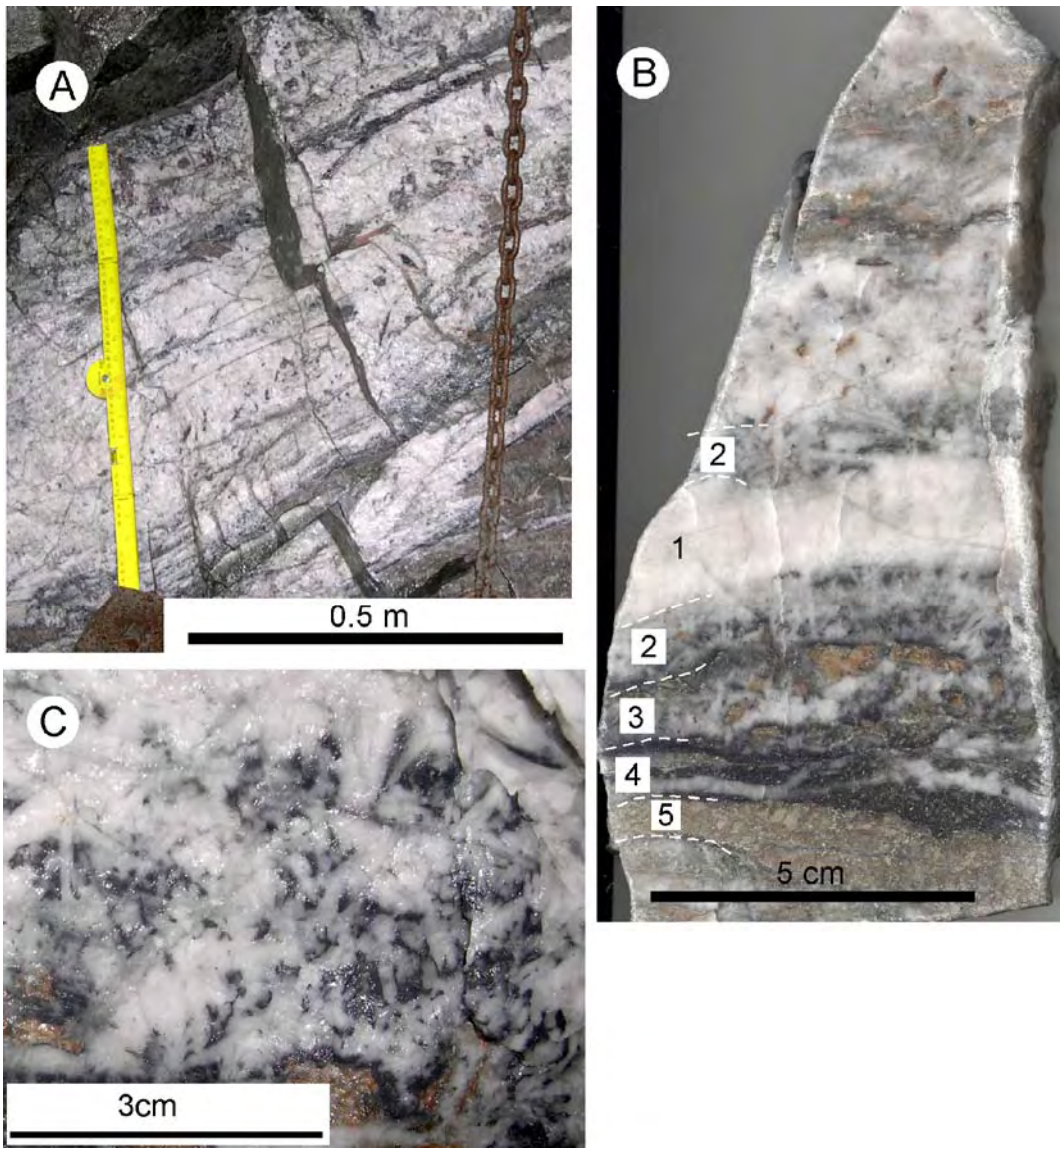

Photo 48. A) Close-up view of vein 4206-S3. Crude banding defined by layers and bands of darker and lighter quartz, slabs and angular fragments of host mafic syenite. B) polished slab from the same part of the vein, showing crustiform-like layering. 1, massive white quartz; 2, randomly oriented prismatic quartz crystals (0.5-1.5 cm long) enclosed in darker matrix that (based on microscopic observations) consists of fine-grained (0.05-0.1 mm) quartz with minor feldspar, sericite, carbonate, and fine opaque "dust" (0.01-0.02 mm); 3, same as 2, but also includes angular mafic syenite clasts; 4, dark grey fine-grained quartz (0.05 mm) with approximately 50% opaque non-reflective particles, and minor feldspar, carbonate, and sericite; 5, sliver of strongly sulphidized (pyrite) mafic syenite. C) a close-up view illustrating characteristic relationships of white and dark quartz in the same part of the vein. Dark fine-grained quartz encloses randomly oriented coarse prismatic quartz crystals or fills intersticies between them.

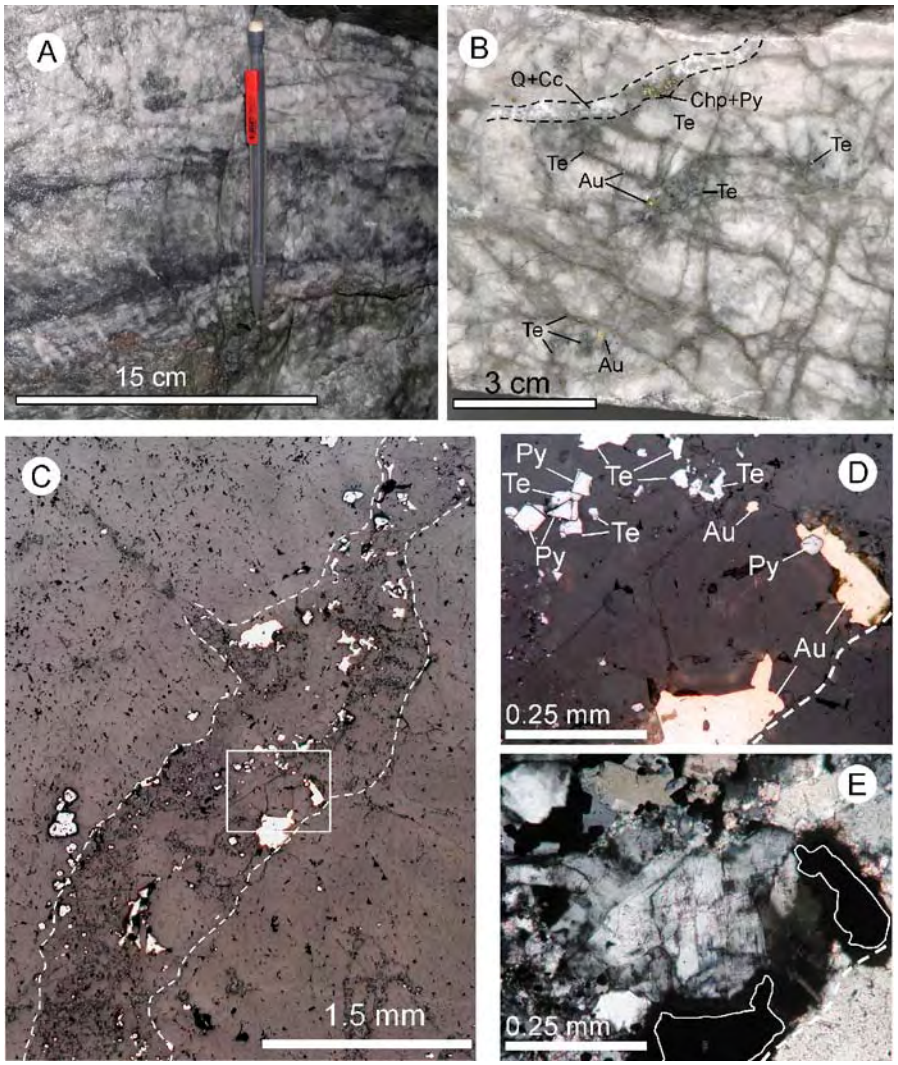

Photo 49. Fracturing and late vein filling in vein 4206-S3 (area corresponding to left-hand bottom part of Photo 46). A) general view of strongly fractured quartz, with late filling aggregate along fractures. B) polished slab from the same area. Gold (Au) and tellurides (Te) tend to occur along the late fractures filled with dull greenish grey (dark on the photo) fine-grained material. Under the microscope, this late vein filling consists of fine-grained quartz, feldspar (most probably K-feldspar), carbonate, and sericite. Note also late quartz-carbonate veinlet (Q-Cc) with pyrite and chalcopyrite (Chp+Py). C) photomicrograph (reflected light) of one of the dark veinlets from photo B. Note concentration of metallic minerals (pyrite, gold and tellurides) in the veinlet (rectangle marks the area of photos D and E). D-E) photomicrographs (respectively, refected light and transmitted light, cross nicols), representing magnified veiws of the rectangular area from photo C. Metallic minerals include gold (Au), tellurides (altaite, Te), and pyrite (Py). Gold is intergrown with feldspar (E, centre of the photo) that shows grid-like twinning characteristic of K-feldspar.

Classifying gold-bearing veins of the Kirkland Lake camp in conventional "fault-fill vein vs. extensional vein" nomenclature (e.g., Robert and Poulsen 2001) is not simple, primarily because of lack of discrete, texturally distinct vein populations. However, it is reasonably clear that steeply (≥ 60º) dipping veins associated with the Main Break, the '04 Break, and similarly oriented hanging-wall veins should be classified as fault-fill veins, based on their close association with and generally parallel orientation to faults, as well as on locally developed vein-parallel foliation in the immediate wall rocks (e.g., Photo 41).

Previously, Thomson et al. (1950) interpreted moderately (about 45º) south-dipping subsidiary veins as extensional veins in the hanging wall of the Main Break reverse fault. The relatively shallowly dipping hanging-wall veins observed at the Macassa Mine in this project, and thus, probably similarly oriented veins at other mines, are unlikely to be extensional. Near-horizontal orientation is expected for extensional veins associated with steep reverse faults (e.g., Robert and Poulsen 2001), whereas at Macassa, many of the veins that are considered shallowly dipping, dip approximately 30-45º south. An even steeper dip angle (roughly 55º-60º) is characteristic of the Teck-Hughes "E" vein that can be remotely observed in a steep wall of a small open pit (Photo 50). There is little or no textural distinction between shallow and steep veins, and textures diagnostic only of extensional veins such as mineral fibres orthogonal to vein walls are not found. Many of the observed veins are spatially associated with and are parallel to minor subsidiary faults (e.g., 4206-S3, "E" vein, Photos 46 and 50), or are controlled by re-activated pre-existing surfaces, such as bedding planes (e.g., 4512, 4713, 5030), or intrusive contacts (4744). Features resembling dilational jogs associated with reverse movement along bedding-parallel slip planes were observed in vein in stope 5030. Although extensional opening mechanism may have played a role locally, it appears more appropriate to interpret gently to moderately dipping (roughly 30-45º) hanging-wall veins as fault-fill veins associated with minor subsidiary structures and reactivated bedding planes and lithological contacts.

Photo 50. Remote view of the Teck-Hughes "E" vein in the proximal hanging wall of the Main Break (looking to the west, old stope on the top is about 1.5 m wide). The vein is hosted by a sharp, most likely brittle, fault or fracture that dips about 55º south (centre of the photo).

METALLIC MINERALS

The mineralogy of Kirkland Lake ores is described in detail by Todd (1928) and Thomson et al. (1950), and only macroscopic observations and pilot microscopic study of 15 samples were done in this project. Gold is accompanied by tellurides (altaite, calaverite, petzite, and coloradoite; Todd 1928; Thomson et al. 1950). Other metallic minerals include pyrite, chalcopyrite, minor sphalerite and very rare arsenopyrite.

Among tellurides, altaite is the most abundant. Milling investigations of two bulk ore samples from the Lake Shore Mine showed that gold-bearing tellurides account on average for 11-19% of the total gold (Thomson et al. 1950). As discussed in the section on geochemistry of gold-bearing veins, relative proportions of native gold vs. telluride gold probably range broadly. Although some gold is associated with pyrite in altered host rocks (Thomson et al. 1950), economically significant gold mineralization is related to gold and tellurides contained in quartz veins.

VEIN-FILLING TYPES

In all veins examined in this study, multiple generations of quartz distinguished by various shades of grey are present. Previously, Todd (1928) and Thomson et al. (1950) documented early white, and later darker generations of quartz. Dark quartz was identified as being better mineralized than the "practically barren" white quartz (Todd 1928, p.67).

A brief petrographic study of quartz vein samples shows that the white quartz that constitutes the bulk of vein fillings is medium to coarse crystalline. Quartz crystals are largely anhedral, and less commonly subhedral to euhedral. The most common grain size is 1-3 mm, and some euhedral to subhedral prismatic crystals are up to 10-20 mm long. Abundant fluid inclusions, including 3-phase aqueous-carbonic, are hosted by the quartz crystals. Orientation of large euhedral-subhedral prismatic crystals is either random, or at high angles to vein walls. Interstices between prismatic crystals are commonly filled with finer-grained darker quartz, and some prismatic quartz crystals are enclosed in the darker quartz matrix (see below). The high-angle orientation of quartz crystals to vein walls, although not equally well-defined, was observed in practically all types of veins (e.g., '04 Break-associated steep veins 4940 and 3829; steep Tech Hughes #1 vein, steeply north-dipping hanging-wall vein 4528; shallowly to moderately south-dipping hanging-wall veins 4206-S3 and 4512). In some breccia veins, wall-rock fragments are overgrown by radiating prismatic quartz crystals.

The darker (grey to almost black) vein filling consists of distinctly finer (0.01-0.1 mm) quartz (Photo 51) accompanied by variable amounts of sericite, carbonate and feldspar (e.g., 4206-S3). The variably intense dark coloration appears to be largely due to the presence of fine opaque particles or clots (0.01-0.05 mm, Photo 51 B, D). Their presence in the fine-grained aggregate and absence in the coarse quartz crystals is particularly well seen in transmitted light with the conoscopic condenser lens that makes fluid inclusions in large "white" quartz crystals invisible. In polished thin sections, these opaque particles are non-reflective (Photo 51B,C,D). They may represent molybdenite or graphite flakes that are too small and are not sufficiently polished to be reflective, or they may consist of a non-crystalline carbonaceous substance, perhaps amorphous carbon. Very fine (0.005-0.01 mm) brown titanite (?) was seen in the dark fine-grained quartz in samples from vein 4206-S3.

The relationships between the dark vein fill and the coarser white quartz vary. In the cataclastic parts of Teck-Hughes #1 vein, fine-grained (0.01-0.02 mm) dark quartz-sericite (sericite > 50%) aggregate cements angular fragments (0.3-1.5 cm) of lighter quartz (Photo 45). Gold and tellurides (0.01-0.02 mm) are present mainly in the dark sericite-rich matrix, and less frequently, in quartz fragments.

In vein 4206-S3, grey to dark grey, fine-grained (0.03-0.1 mm) quartz with minor K-feldspar (?), sericite, carbonate and variably abundant opaque particles forms discrete bands (2-5 mm) and occurs as matrix enclosing randomly oriented white subhedral prismatic (0.5-1.5 cm long) quartz crystals, or filling interstices between them (Photos 48, 51). The dark quartz occurs in multiple concordant bands parallel to vein contacts, and the relative abundance of dark and white vein fillings defines a characteristic crude layering, along with the abundance of host rock fragments (Photo 48B,C). In other veins (e.g., 4528, 4506, 3829), the darker aggregate of fine quartz, subordinate carbonate, sericite, and opaque particles

similarly forms a matrix that encloses larger prismatic white quartz crystals oriented randomly or at high angles to vein walls.Very fine-grained gold, tellurides and pyrite occur in the dark fine-grained vein filling aggregate (Photo 51C,F). The material of an irregular-shaped grey quartz pod along the ’04 Break at Macassa stope 4940 (Photo 40, bottom part) consists almost entirely of very fine-grained (0.01-0.05 mm) quartz, with subordinate coarser (0.1-0.5 mm), typically strained, anhedral quartz grains, patches of carbonate, sericite flakes, and some opaque grains.

A distinct vein filling type is documented in vein 4206-S3 where macroscopically visible gold and tellurides are associated with a network of thin (1-3 mm) greenish grey to dark grey fracture-fill veinlets (Photo 49). Under the microscope, these veinlets consist of fine (0.02-0.1 mm) quartz, relatively abundant feldspar (optically identified as K-feldspar, based on characteristic grid-like twinning pattern, Photo 49E), carbonate and sericite. Very fine-grained (0.002-0.01 mm) titanite (?), and non-reflective opaque particles similar to those described earlier are also present. Gold and tellurides occur both within these veinlets and in proximity to them, along fractures in white quartz. Petrographic (optical) identifications show that feldspar may actually be more abundant than quartz in these late veinlets.

The occurrence of the dark, fine-grained quartz as a matrix enclosing coarser white quartz crystals, and concordant layering of dark and white quartz within individual veins (e.g., vein 4206-S3, Photo 48), imply that the dark quartz is unlikely to constitute a discrete generation that entirely postdated the white quartz. More probably, the fine grained dark quartz was deposited multiple times, perhaps during episodes of relatively rapid precipitation, alternating with periods of more slow, unrestricted growth of coarser quartz crystals. Such variations in the precipitation regime may be related to fault-valve mechanism, in which fault slip, brecciation, and associated pressure drops induced quartz precipitation. Presently available data are insufficient to confirm this possibility, and the origin of vein-filling types deserves further investigation because of its potential implications for gold deposition processes. The presence of gold and tellurides in the dark fine-grained vein-filling aggregate indicates that events or mechanisms that controlled precipitation of the dark quartz could also have triggered gold deposition.

The presence of euhedral-subhedral prismatic quartz crystals oriented randomly or at high angles to vein walls and enclosed in the darker fine-grained quartz matrix indicates unrestricted growth of prismatic quartz in fluid-filled cavities that were later filled with finer-grained quartz. This assemblage, along with prismatic quartz crystals radiating from angular wall-rock clasts, constitutes an open-space-filling texture. Although the occurrence of open-space-filling textures in fault-fill veins is generally atypical, they have been documented at several gold deposits (e.g., Hagemann et al.1992; Robert and Brown 1986; Boullier and Robert 1992). Such textures are particularly common at relatively shallow (i.e., epizonal, Hagemann and Cassidy 2000) systems, due to low effective confining pressure (e.g., Hagemann et al. 1992). The presence of open-space-filling textures in variably oriented veins of the Kirkland Lake gold deposit, and the association of veins with largely brittle faults imply that hydrothermal activity occurred at relatively shallow crustal levels. Fluid pressure may have played an important role in the opening of both shallowly and steeply dipping veins, which can at least partially explain textural similarities between the two vein types.

Post-Ore Veining

Non-auriferous post-ore veins occur along the ore-controlling faults (the Main Break and the ‘04 Break) and major post-ore faults. The post-ore veins either cut across or are parallel to auriferous quartz veins. They generally consist of translucent quartz and pink or white carbonate, commonly with films and bands of dark green chlorite along vein selvages, and locally with coarse (3-5 mm) rosettes of chlorite within veins. Some veins contain clots and patches of pyrite and chalcopyrite. Late, post-ore barite and gypsum (selenite) veinlets are also common.

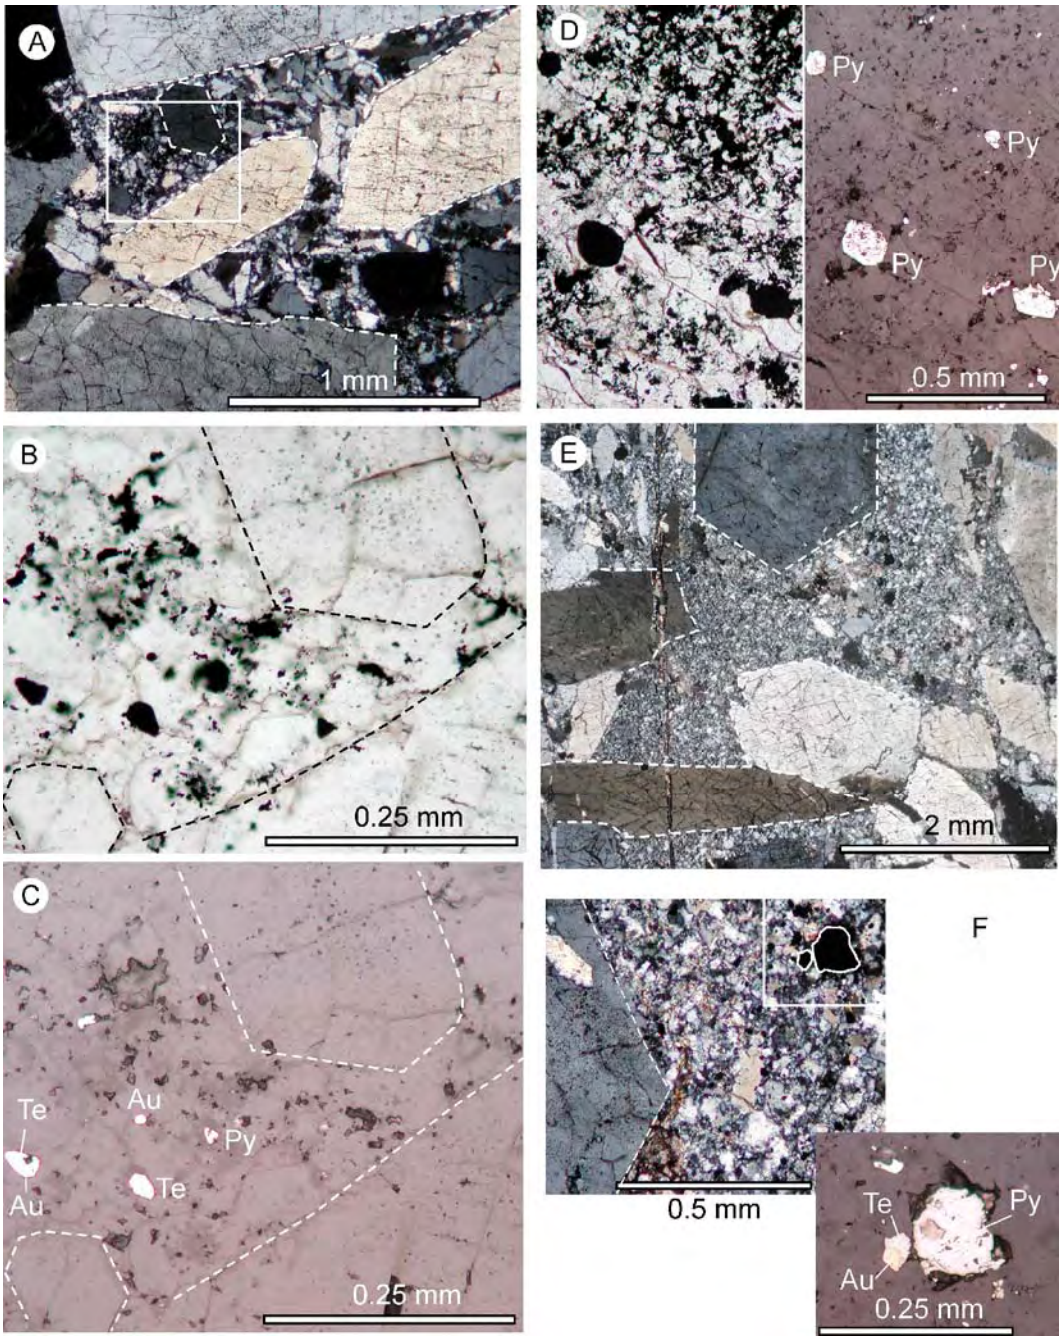

Photo 51. Photomicrographs illustrating vein filling types in gold-bearing quartz veins. Photos A-D depict vein 4206-S3, material from layers marked "2" and "4" on Photo 48B; photos E and F are of vein 4506. A) Fine-grained quartz (dark matrix on Photo 48B, layers marked "2", and on Photo 48C) filling interstitial spaces between coarser euhedral prismatic quartz crystals (white on Photos 48B-C). Transmitted light, cross nicols. B) Enlarged view of a rectangular area of photo A, large euhedral quartz crystals are outlined by dashed lines, note presence of opaque "dust" in fine-grained quartz aggregate (transmitted plane-polarized light). C) The same area as in B, reflected light. Very fine-grained gold (Au) and altaite (Te) occurring in the fine-grained quartz aggregate; opaque "dust" visible on photo B is non-reflective. D) (left-hand: plane polarized transmitted light; right-hand: reflected light) dark fine-grained quartz (from layer marked "4" on Photo 48B) with approximately 50% opaque non-reflective particles. E and F, vein 4506. E) fine-grained matrix consisting of quartz, sericite, carbonate, and possibly subordinate feldspar, enclosing euhedral prismatic quartz crystals (outlined by dashed line). Note variable orientation of euhedral quartz crystals. F) enlarged view of the fine-grained matrix containing gold (Au) and altaite (Te), along with pyrite (lower right-hand). Larger euhedral quartz crystal is outlined by dashed line.

Wall Rock Alteration

Macroscopic observations at the Macassa Mine show that hydrothermal alteration associated with gold-bearing quartz veins includes variable but generally moderate carbonatization, minor sericitization, and local silicification. Rocks in immediate proximity to gold-bearing quartz veins and wall-rock clasts within the veins invariably contain disseminated pyrite. Red coloration of syenitic rocks and some varieties of tuffs is due to very fine dust of hematite, especially in K-feldspars, however it is not completely clear whether this hematitization is directly related to gold mineralization. Preliminary microscopic observations of quartz vein samples show that hydrothermal K-feldspar, replacing primary magmatic K-feldspar, may be present in mafic syenite in proximity to veins, as well as in mafic syenite fragments enclosed in vein matrix. In the central part of the Kirkland Lake camp (Lake Shore, Wright-Hargreaves, and Teck-Hughes mines), veins are locally accompanied by rather strong wall-rock sericitization. Several lines of evidence suggest that this sericitization is closely related to gold mineralization. Within veins, sericite is commonly associated with gold. In a cataclasized part of the Teck-Hughes #1 vein, the sericite-rich matrix hosts gold and telluride grains (Photo 45D,E). In a gold-bearing quartz sample from the Lake Shore property (sample LS, Appendix A), fragments of strongly sericitized syenite porphyry and monomineral sericitic streaks are enclosed in quartz vein matrix, and some sericite streaks contain gold and tellurides. On the Mud Break ouctcrop, a relatively thick and intense sericite alteration halo is symmetrically distributed on both sides of a thin quartz veinlet (Photo 38B). Previously, Thomson et al. (1950, e.g, p.122) also described sericitic alteration in the central part of the camp as closely related to gold mineralization.

Patches (2-5 cm) of bright green mica, possibly a vanadium-rich variety (roscoelite), were observed in sericitized and silicified syenite porphyries within the Mud Break mineralized zone. As discussed in a section on geochemistry of gold mineralization, elevated V values in some gold-bearing samples from other locations in the Kirkland Lake camp may also indicate the presence of vanadium mica.

Strong carbonatization in cataclastic bands along the Main and ’04 breaks is equally present in mineralized and unmineralized fault segments, and probably is largely unrelated to mineralization (see Thomson et al. 1950). Data in Kerrich and Watson (1984) show the addition of CO_2 along breaks not accompanied by elevated gold values, whereas no significant CO_2 addition is observed along some gold-bearing veins. This similarly indicates that although strong carbonatization occurred along major faults, it probably was not an essential part of the mineralizing process. Also, intensive chloritization (dark green chlorite) along fault slips, characteristic of the Macassa Mine, appears to be unrelated to gold mineralization, for the following reasons. Dark green chlorite is clearly not a major component of mineralized quartz veins. Apart from locally present chloritized pyroxene in mafic syenites, there is no pronounced bulk chloritization of host rocks along mineralized veins and of rock fragments incorporated into the veins. If chlorite is present in veins, it always texturally postdates mineralized quartz, that is, it coats fractures or occurs in selvages of crosscutting late barren quartz-carbonate veinlets (e.g., Teck-Hughes vein #1). None of the observed mineralized banded veins containing wall-rock slivers, probably incorporated through the crack-seal mechanism, actually contains fragments of chloritic gouge or chloritized slip bands. On the contrary, in late, barren, quartz-carbonate veins and veinlets, dark green chlorite is commonly present as films in selvages and, in places, as rosettes within the veins (e.g., stope 4247, Macassa Mine). Thus, intense chloritization along fault slips is probably associated with a late post-mineralization hydrothermal event. Hicks and Hattori (1988) documented the same post-dating nature of chloritic gouge with respect to the auriferous North vein in the central part of the camp.

Sense of Movement Along the Kirkland Lake Fault and ‘04 Break

Features potentially indicating the sense of movement along ore-controlling faults include oblique internal foliation in fault zones (the Main Break at surface and ‘04 Break in stope 4528 MCF) and striations on chloritic slip surfaces of the Main Break and ‘04 Break. Striations on chloritic slips reflect post-ore movements, because intensive chloritization along fault postdated gold mineralization. Relatively shallow-plunging striations probably record post-diabase strike-slip movements (see below).

Oblique foliation within sericitic deformation bands along the Main Break on the Lake Shore property, indicative of reverse-dextral slip, could reflect syn-mineralization movements. Sericitization is related to formation of gold-bearing veins, and foliation of sericitic deformation bands may be broadly synchronous with mineralization, although post-mineralization origin is also possible. The weakly developed oblique foliation in the ‘04 Break (stope 4528 MCF), compatible with reverse slip, may reflect pre-, syn- or post-mineralization movements.

Previously published estimates on the magnitude of the slip movements along the faults are based on analyses of displaced markers. These estimates suggest reverse (south side up) sense of movement on the Main Break. Using the tuff-conglomerate contact on the the Teck-Hughes and Kirkland Lake Gold properties, Todd (1928) estimated a vertical movement of 610 m. Hopkins (1940) analyzed the shape of the syenite intrusion at the Kirkland Lake and Macassa mines and proposed a 17º clockwise (facing north) rotational movement of the hanging wall, with the pivotal point located at about 1000 m below the surface near the western boundary of the Wright-Hargreaves Mine. Thomson et al. (1950) summarized displacement data for various markers across the camp: a pipe-like syenite body at Macassa, Kirkland Lake Gold, and Teck-Hughes (about 450 m, reverse); small quartz-feldspar porphyry intrusions at Lake Shore (400-490 m, reverse); and the syenite porphyry-sandstone contact at the Toburn Mine (about 105 m, reverse). Thomson et al. (1950) concluded that the Main Break had a rotational reverse movement, with increasingly larger displacement in the west, and this movement pre-dated mineralization. Late displacements of diabase dikes are invariably strike-slip sinistral, reaching 25-30 m at Teck-Hughes and Lake Shore, roughly 0.75 m at the eastern part of Macassa, and about 2.5 m at Toburn (Thomson et al. 1950). Shallowly plunging striations on chlorite-coated slip planes of the Main Break and ’04 Break are probably related to these post-diabase movements.

Kinematic indicators documented in the present study are in general agreement with previously documented predominantly reverse movements. The inferred dextral component can also be reconciled with these previous studies given the complex geometry of most markers. It is also possible that reverse-dextral movements occurred during some short episodes, whereas the overall displacement was largely reverse (south over north). The presence of an oblique reverse-dextral-slip foliation in sericitic bands also provides information on the relative timing of fault movements and mineralization. Sericitization accompanied gold mineralization, and thus the movements were not entirerely pre-ore as proposed by Thomson et al. (1950) but must have overlapped with or posdated mineralization.

Narrows Break Mineralization

Considerable confusion exists over the location of a structure called “Narrows Break” (Lackey 1990, p.74). The name is currently applied to mineralization exposed in a stripped area about 360 m north-northwest of the former Kirkland Lake Gold Main shaft and roughly 340 m north of the Main Break (S. Carmichael, Kirkland Lake Gold Inc., personal communication, 2004; Figure 33). The same gold occurrence is named “Powderhouse Shear Zone” by Lackey (1990).

Mineralization occurs as a zone of sheeted veinlets and pervasive iron-carbonatization and sulphidation (pyrite) localized at the southern contact of an augite syenite sill intruded in Timiskaming sandstones and reworked tuffs. Timiskaming rocks strike about 085º-095º (locally to about 110º-120º), dip 50-60º (30-40º in places) south (Figure 34). Steep discrete northeast-trending cleavage S4 intersects bedding from about 30º counterclockwise to almost orthogonally (Figure 34). Southwest-plunging folds with axial planar S4 are relatively rare and generally poorly developed. No major ore-controlling fault-like structure is observed in the stripped area. The 1-2 m wide, roughly 35 m long, northeast-trending (about 050º) assay-defined ore zone marked for bulk sampling by Kirkland Lake Gold Inc. geologists roughly corresponds to a swarm of thin (1 to 10 mm) sheeted carbonate-quartz veinlets hosted by carbonatized and sulphidized coarse- to medium-grained sandstones (Photo 52) and mafic syenites (near the northeastern end). Similar veinlets are also observed in other parts of the stripped outcrop. Within the ore zone, most veinlets strike 030º-050º and dip steeply southeast (Figure 34). The veinlets are typically zoned: carbonate lines the veinlet walls and quartz fills the center of the veinlets. Individual quartz and carbonate crystals are commonly oriented at high angles to veinlet walls. Gold, occasionally macroscopically visible, occurs along veinlet selvages (Photo 53), and may also be present in the sulphidized host rocks. Average gold grades of the ore zone are relatively low, on the order of 0.15 ounces per ton over 5 feet (about 5 g/t over 1.5 m) (M. Sutton, Kirkland Lake Gold Inc., personal communication, 2004), although 2 grab samples from the sheeted veinlet zone returned 60 and 90 g/t Au (Appendix A). Veinlets (in the ore zone and throughout the stripped outcrop) show variable relationships with S4. Some veinlets are hosted by cleavage planes, others crosscut them, and some are folded with axial planar S4. This indicates broad temporal overlap between veining and D4 deformation. The Narrows Break mineralized zone differs from typical Kirkland Lake gold mineralization by its lack of large veins, distinctly higher proportion of carbonate in vein material, stronger wall-rock carbonatization, and lack of tellurides and molybdenite.

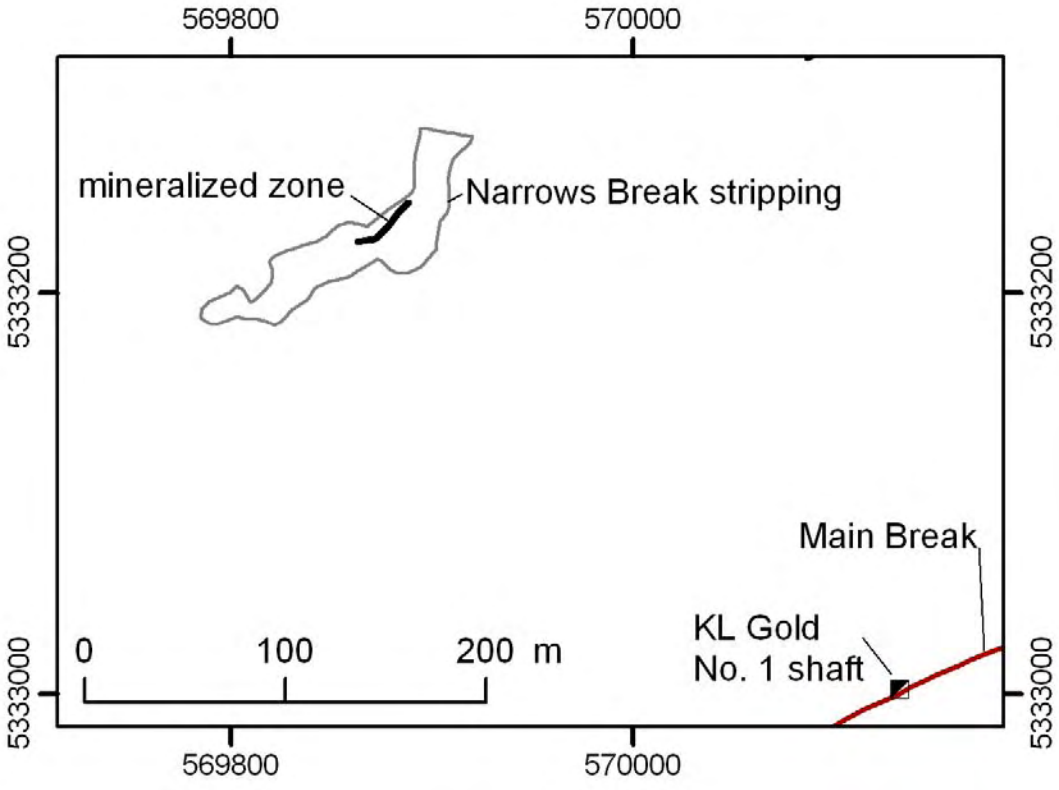

Figure 33. Location of the Narrows Break stripping and mineralized zone.

D Zone

The D zone was recently discovered by Kirkland Lake Gold Inc. in the Macassa shaft #3 area at a depth of 970-1050 m, and is presently considered one of the most promising exploration targets at the Macassa Mine. The zone strikes 010-020º and dips about 45º east. In summer-early fall 2004, drifting on the 3400-foot level of Macassa Mine was following the unmineralized to weakly mineralized portion of the structure, but the high-grade interval was not reached by the end of the 2004 field season. In the drift, the unmineralized to weakly mineralized part of the D zone is represented by a sharp slip surface in weakly strained conglomerates. Northeast-plunging (025-035º/25º) and approximately dip-parallel slickensides were observed in two locations. The slip surface is coated by chlorite and accompanied by a 0.4-0.5 m wide bleached zone with disseminated pyrite. A 1-1.5 m wide swarm of thin (1-2 cm) quartz-carbonate veinlets occurs in the immediate footwall of the structure. These veinlets are somewhat similar to those observed on the Narrows Break stripping: white carbonate lines the walls and quartz fills central parts. According to the mine geologists, these veinlets are only weakly auriferous, and thus are probably not representative of the predominant mineralization style of the high-grade D zone. A steeply dipping, northeast-trending (030º-040º/70º) foliation, which probably corresponds to S4, is defined by rather weak pebble flattening in the conglomerates. The zone appears to crosscut the foliation, although this relationship is not diagnostic, primarily because of weak development of the fabric.

Intramineral Dikes

Still (2001) described felsic green dikes crosscutting gold-bearing veins, containing quartz fragments, and locally mineralized, with grab sample Au values reaching approximately 18 g/t. In the present study, dikes occurring in immediate proximity to gold-bearing veins were observed at the Macassa Mine (Photos 54 and 55). Direct contacts between the dikes and quartz veins are common, but in most cases cannot be interpreted in terms of the relative timing of the emplacement of the dikes and quartz veins. Dikes and veins are approximately parallel and are hosted by the same fractures. Contacts are in most cases sharp, and virtually all dikes are strongly sericitized, carbonatized, contain disseminated pyrite and show elevated gold values (e.g., 30-135 ppb in samples collected in this study, Appendix A). Relatively unaltered (note low CO_2 of sample 4528D, Appendix A), 0.2 to 0.7 m thick dike occurs along the north-dipping gold-bearing vein in stope 4528 MCF (eastern part, Photo 55). Splintery injections of dike microapophyses into vein quartz, and quartz fragments (0.3-1 cm) enclosed entirely in the matrix of the dike are seen in samples collected from this stope (Photo 56). In addition to that, the angular fragments of host mafic syenites enclosed in quartz are strongly sulphidized, whereas the dike along the vein contact, and dike microapopophyses injecting quartz, show weak or no sulphidation. These relationships imply that the emplacement of the dike postdated at least some phases of vein formation. This confirms the intramineral nature of the dikes (Still 2001). In addition to these dikes, texturally and compositionally identical planar intrusions were documented at several locations at surface. As shown below, the dikes are petrographically and geochemically distinct from the other intrusions and constitute a separate magmatic phase. The following section provides a brief description of these small planar intrusions that are for descriptive purposes termed “intramineral dikes”.

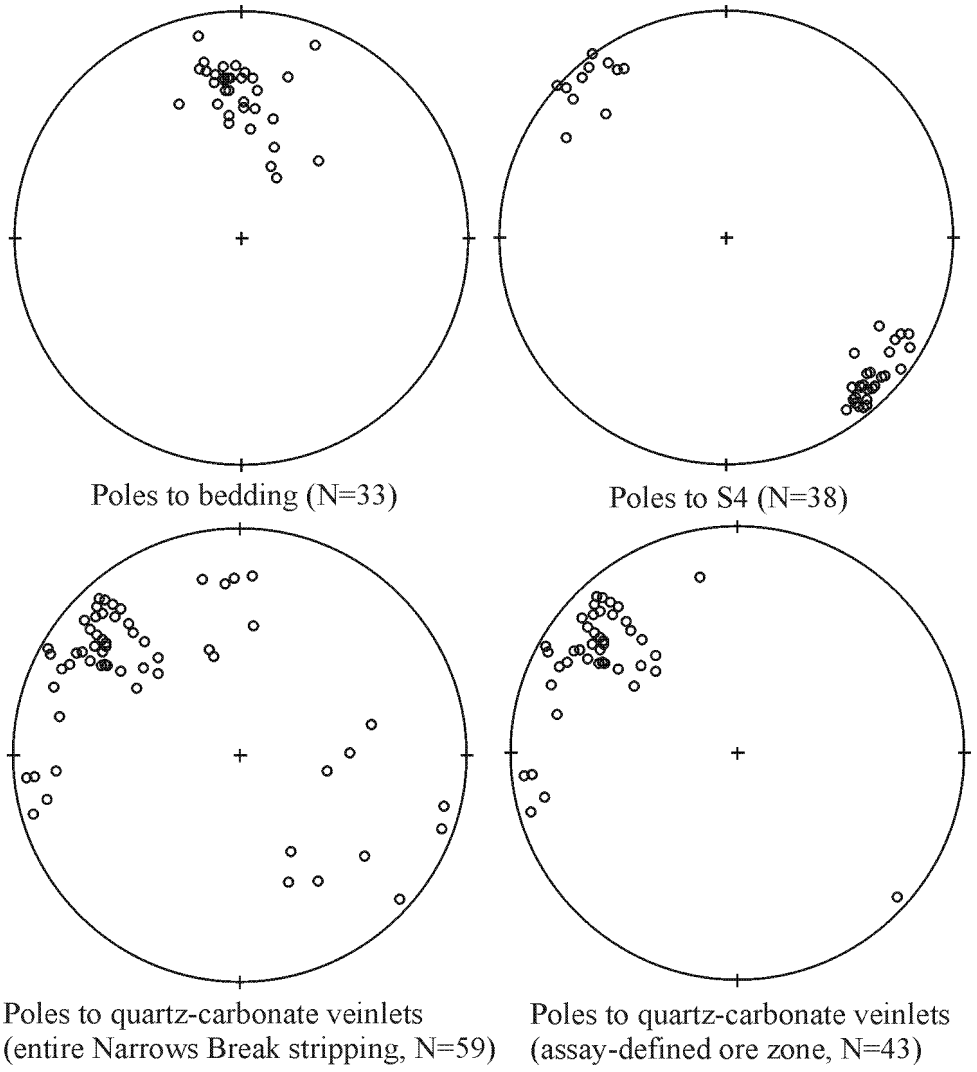

Figure 34. Stereonet plots for the Narrows Break stripped outcrop: bedding, S4 and quartz-carbonate veinlets (right-hand bottom plot corresponds to the assay-defined ore body marked for bulk sampling by Kirkland Gold Inc. geologists).

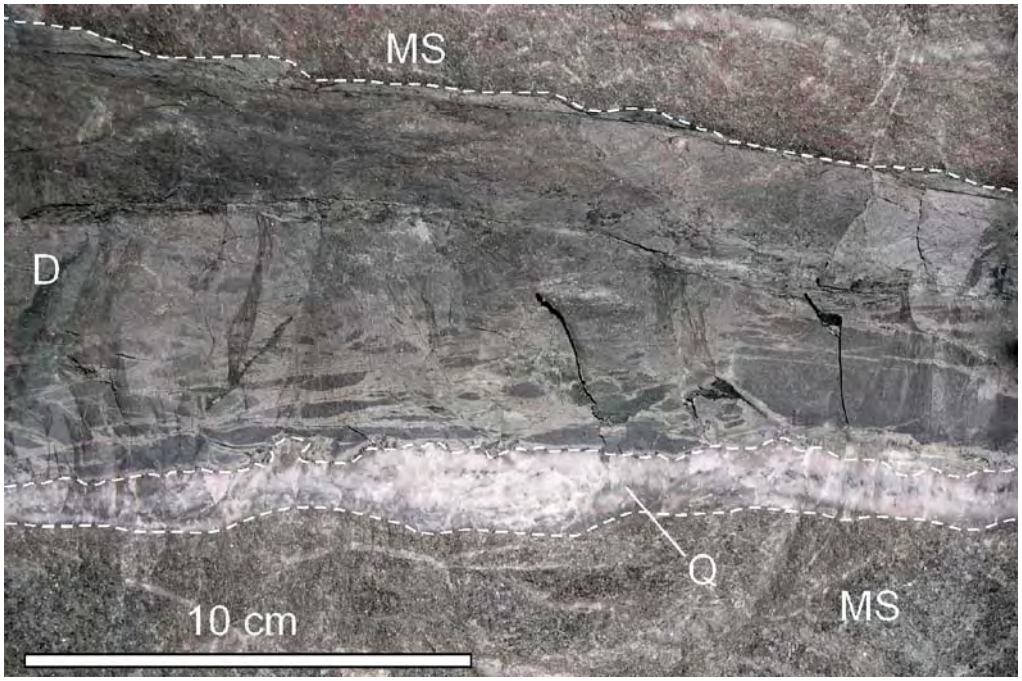

Photo 55. Dike on the back of stope 4528, Macassa Mine. Dike has a sharp jagged contact with the vein and there is no sulphidation of the dike along the contact.

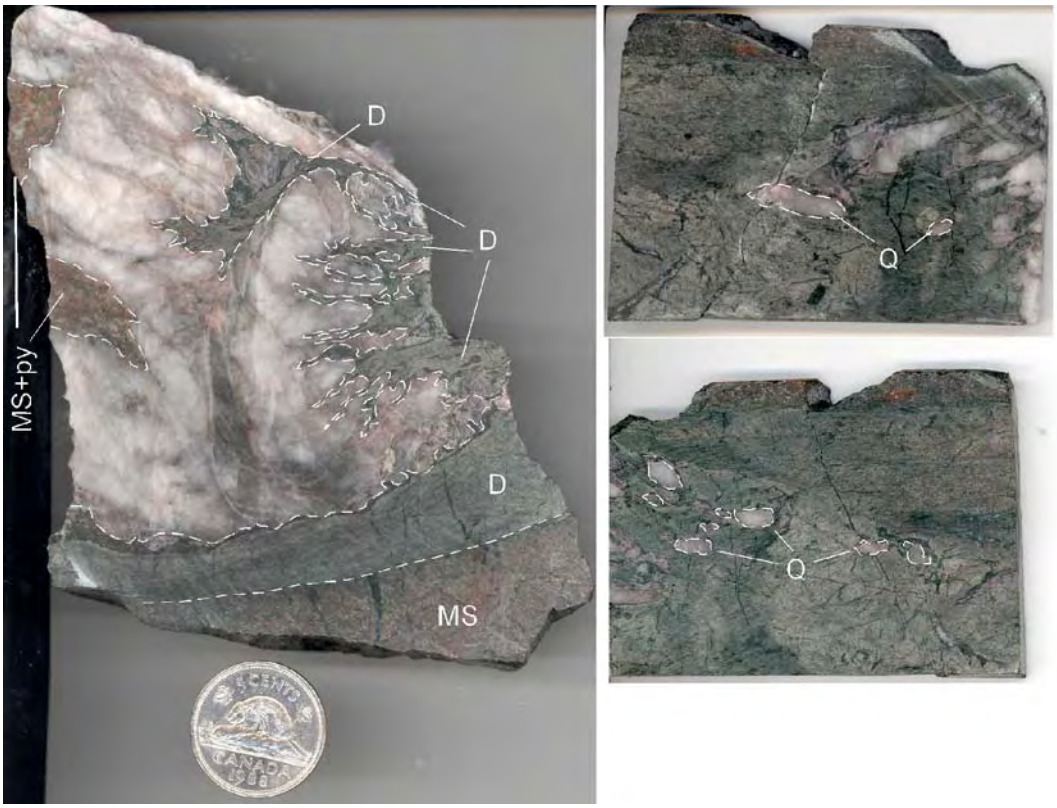

Photo 56. Cut sample of the dike-vein contact from stope 4528 (Macassa Mine). Left column: splintery injections of dike material (D) into the quartz vein; fragments of mafic syenites enclosed in the vein (left-hand side) are strongly sulphidized (MS+py) whereas 1-3 mm thick dike injections do not show sulphidation. Right column: fragments of vein quartz (Q) entirely enclosed in the dike matrix. Sample courtesy of D. Quick, Kirkland Lake Gold Inc. The same dike is shown in Photo 55.

The thickness of most intramineral dikes examined underground at the Macassa Mine varies from 0.3 to about 1.5 m, and unusually thin (2-5 cm) dikes occur in places. Their overall orientation is approximately parallel to the ’04 Break, however, local abrupt changes in orientation are common. Altered rocks are typically light grey with variable subtle tints. The relatively unaltered dike from stope 4528 MCF east, is green to dirty greyish green. Macroscopically, dikes exposed in underground workings are either aphanitic or contain small (0.5-2 mm) dull light green flakes of altered mica (?) and, more rarely, light green prismatic pseudomorphs (2-3 mm). Contacts with wall rocks are sharp and frequently have irregular outlines. Immediate endocontacts of dikes are marked by thin (1-3 mm) light-colored rims, probably chilled margins.

Dikes exposed at surface outcrops vary in thickness from a few centimetres to 1-1.5 m. Apart from weathering, they are similar to those observed underground. Thin (2-10 cm) dikes commonly show abrupt changes of orientation. Contacts are sharp and often splintery, with thin microapophyses penetrating wall rocks; angular xenoliths of immediate host rocks are common (Photo 57). Macroscopically, the rocks are largely aphanitic; in one location (station 004VOI1518), dikes contain relatively coarse (roughly 2 mm) possibly xenocrystic biotite grains. Most of the dikes exposed at surface are carbonatized to a variable extent.

In thin section, the least-altered intramineral dikes (e.g., sample 004VOI1518-2) contain 10-20% thin biotite flakes (0.25-0.5 mm) and relatively sparse rounded or ovoid grains (0.25-0.4 mm) completely replaced by fine-grained feldspar. Some dikes also contain relatively coarse (1-2 mm) euhedral prismatic

pseudomorphs of carbonate, chlorite, sericite, ±epidote and secondary acicular amphibole (?). Most likely, these represent altered mafic phenocrysts, perhaps pyroxene. Coarser (1-2 mm) biotite grains present in some dikes are likely xenocrystic as they show signs of resorption. Similar mineral constituents (fine mica flakes, rounded to ovoid feldspar pseudomorphs and euhedral prismatic pseudomorphs), although strongly to completely carbonate-sericite-altered, are recognized in thin sections of intramineral dikes from underground workings.

Geochemical data for 9 samples of intramineral dikes, both from surface outcrops and underground workings, are listed in Appendix A. The whole-rock (total alkali versus silica) composition of these dikes corresponds to trachybasalt to phonotephrite (Figure 35). The rocks are definitely alkalic, although total alkali content and relative proportions of K_2O and Na_2O vary, probably due to alteration. A roughly 10% K_2O content combined with rather low Na_2O in the least altered sample (004VOI1518-2) shows that the dikes probably belong to the potassic rather than sodic type of alkalic rocks. Binary plots of immobile elements and element ratios (Figures 36 and 37) show good clustering and distinct (compared to other intrusive rock types) trace element systematics for these dike samples. This supports macroscopic and petrographic observations, suggesting that the intramineral dikes from underground workings and surface outcrops belong to one coherent group that is distinct both from major intrusive phases and coarse lamprophyre dikes and sills. Primitive-mantle-normalized plots (Figure 38) of intramineral dikes share key similarities with corresponding data of major intrusive phases, including strongly fractionated REE and well-pronounced Nb, Ti, and Sc lows. Most of these features are universally typical for Timiskaming volcanic rocks and related plutons (e.g., Ben Othman et al. 1990), thus, on a big scale, the intramineral dikes probably represent the same magmatic cycle as stratified Timiskaming volcanic rocks and related intrusions.

Most (5 of 6) intramineral dikes observed on surface outcrops are moderately to strongly foliated (S4). Conflicting relationships between the dikes and S4 are observed on outcrop 004VOI1518 (568572E 5333147N, Figure 39, Photo 58), where the folded (F4) bedding-parallel contact of syenite porphyry and tuff is crosscut at high angle by two intramineral dikes that are parallel to axial planar S4. The larger (1-1.5 m wide) dike is pervasively foliated, whereas the smaller (3-5 cm) dike, which changes orientation from axial planar-parallel to bedding-parallel, does not contain foliation. Apart from a difference in intensity of deformation, the dikes are similar petrographically and geochemically (in immobile element systematics). Crosscutting relationships of dikes and the fold (F4), combined with the presence of S4 foliation in one dike and lack thereof in the other, implies that emplacement of the dikes overlapped in time with D4 deformation, and the thin dike largely postdated D4 folding and shortening.

Photo 57. Surface exposure of an intramineral dike, a close-up view (Macassa property, trench on the north-south powerline, south of the Goldthorpe road; station 004VOI1745, 568593E 5332584N). A 3-10 cm thick dike crosscutting syenite porphyry and containing wall rock xenoliths (X).

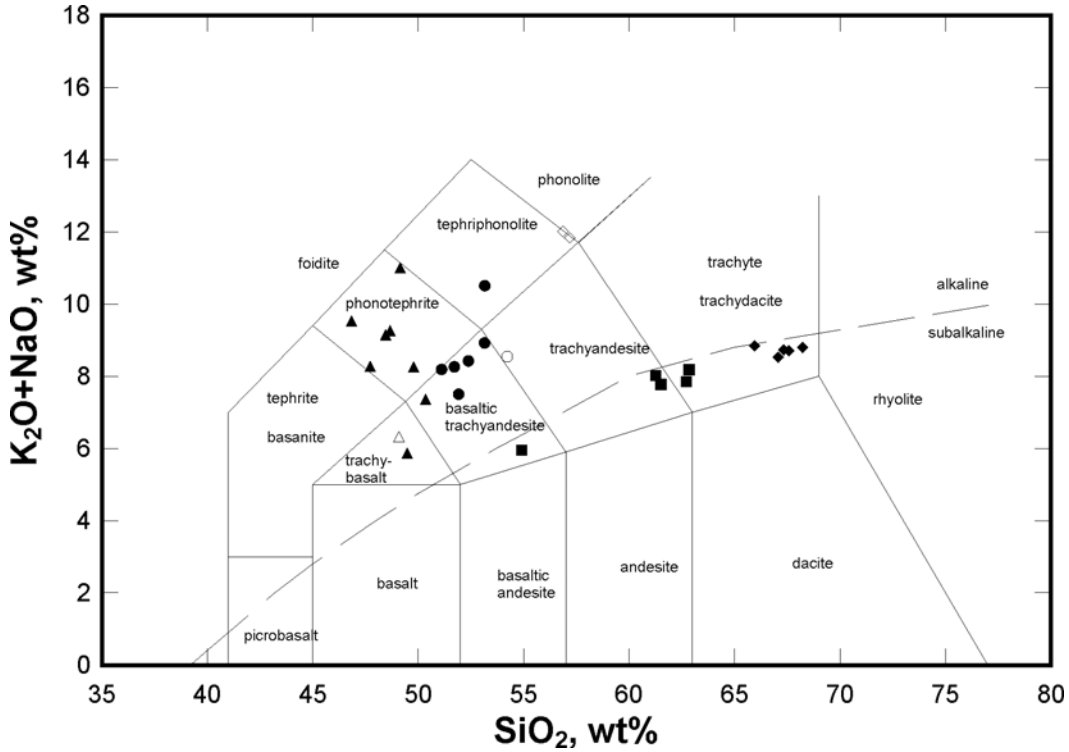

Figure 35. Total alkali vs. silica (Le Bas et al. 1986; Irvine and Baragar 1971) plots of intrusive rocks of the Kirkland Lake camp. Filled diamonds, feldspar-rich syenite porphyries; squares, sparsely porphyritic syenite porphyries; filled circles, mafic syenites; open diamonds, syenites; open circle, trachyandesite (west of the Amikougami Creek fault); filled triangles, intramineral dikes; open triangle, coarse biotite lamprophyre.

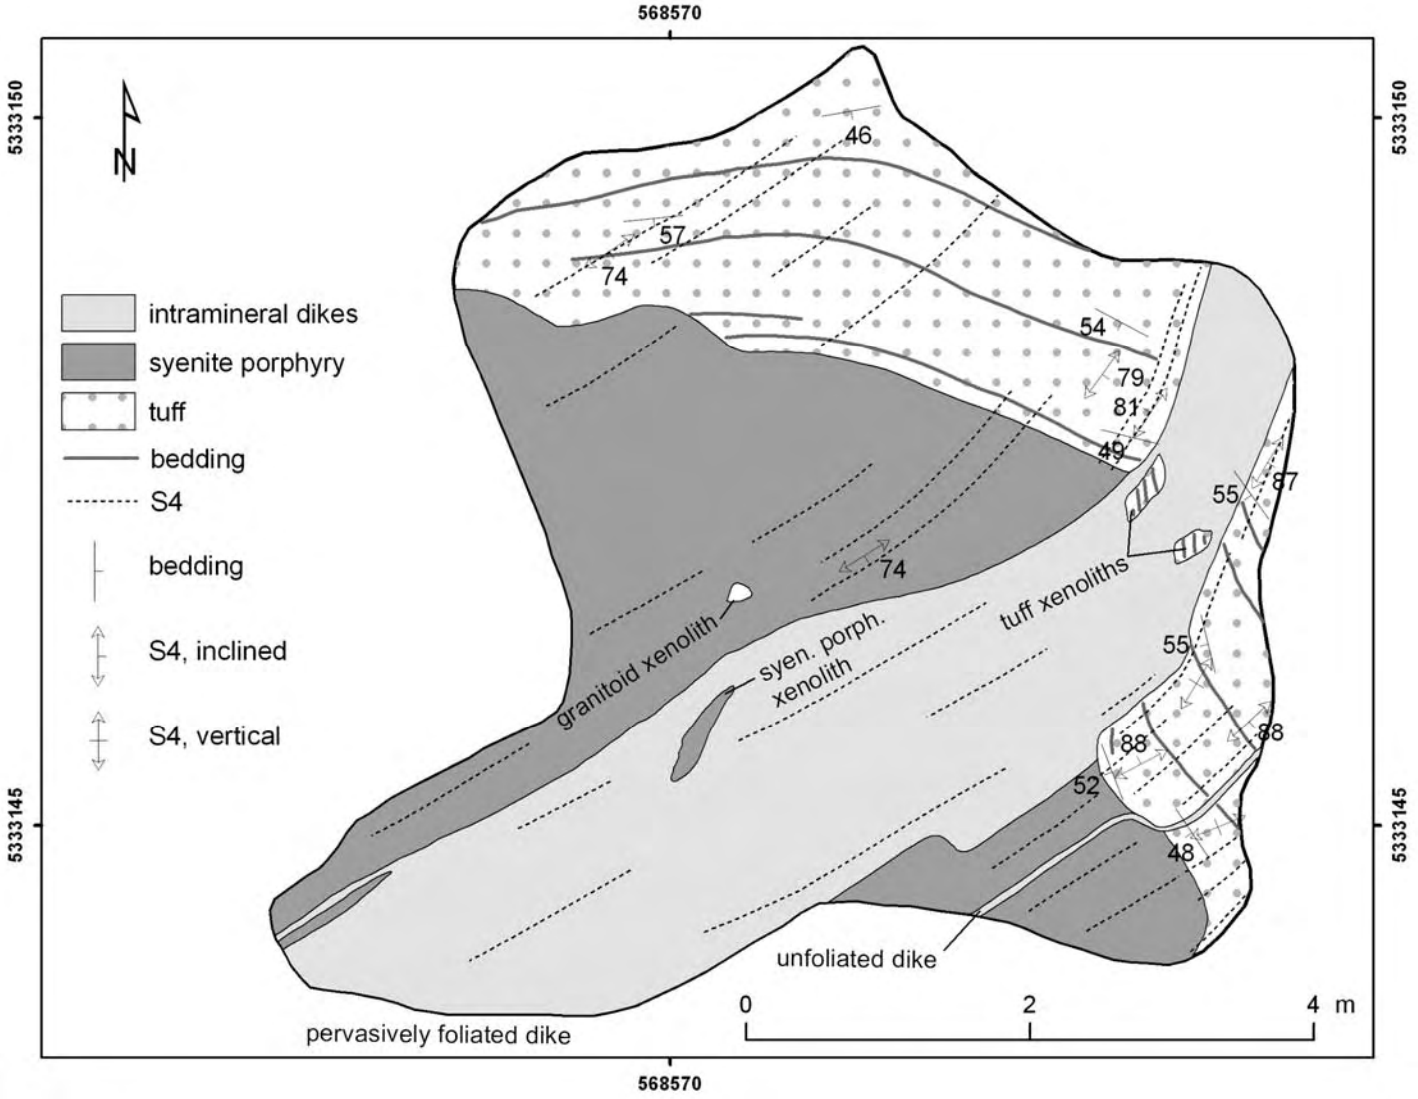

Figure 39. Geological plan of the outcrop 004VOI1518 (568572E 5333147N). See also Photo 58.

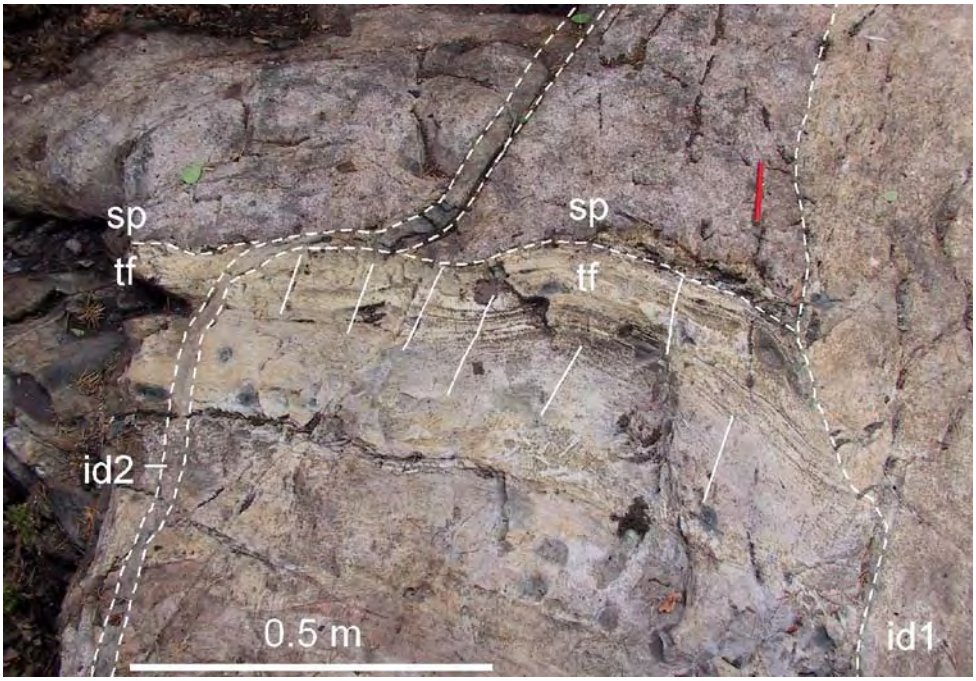

Photo 58. Portion of outcrop 004VOI1518 (area corresponding to the lower right-hand side of Figure 39), looking southwest. Fragment of a folded contact of tuffs (tf) and syenite porphyries (sp) transected at high angle by axial planar S4 cleavage (solid lines). Two S4-parallel intramineral dikes crosscut syenite porphyries and tuffs. The dike on the right-hand side (id1) is pervasively foliated, whereas the thin dike on the left-hand side (a short segment of which is hosted by the tuff-syenite contact plane) is unfoliated. Emplacement of the second dike (small) most probably largely postdated D4 folding.

Relative Timing of Deformation and Mineralization

The exact relative timing of Kirkland Lake gold mineralization and deformation events is not entirely clear. Apparent temporal overlap between the emplacement of the intramineral dikes and D4 (documented at outcrop 004VOI1518) suggests that the formation of the gold-bearing veins at the Macassa Mine could have, at least partially, overlapped with D4. As most intramineral dikes exposed at surface are foliated (S4), gold-bearing quartz veins possibly formed early during D4 and were later deformed.

Syn-mineralization stylolites that host gold and telluride grains in northeast-trending, steeply dipping quartz veins (e.g., stope 4940) are parallel to the regional S4 orientation. The alignment of stylolite teeth approximates the orientation of greatest principal stress (Davis and Reynolds 1996, p.443-444). Horizontal (northwest-southeast) orientation of stylolite teeth in auriferous veins indicates that the veins experienced northwest-southeast shortening (cf. Boullier and Robert 1992), and the occurrence of gold and tellurides along stylolite surfaces suggests that this shortening probably overlapped with mineralization. The orientation of S4 corresponds to the same shortening direction, implying that mineralization could have formed broadly synchronous with D4.

Syn-mineralization cataclasis of the Teck-Hughes #1 vein hosted by a subsidiary north splay of the Main Break (Todd 1928) shows that mineralization was accompanied by movements along host fault structures. The inferred reverse-dextral (south side up and to the west) slip along the primary ore-controlling structure, the Main Break, is also kinematically compatible with regional northwest-southeast

shortening characteristic of D4. Based on the above summarized evidence, we suggest that the high-grade gold-bearing veins of the Kirkland Lake deposit could have formed relatively early in the D4 event, and have been partially overprinted by continuing deformation. Mineralization was accompanied by reverse-dextral to reverse movements along the Main Break. Sheeted veinlets of the Narrows Break mineralized zone show conflicting relationships with the S4 cleavage, and thus their formation was broadly synchronous with D4.

Amikougami Creek Fault

Gold mineralization at the Macassa Mine and Kirkland Lake camp in general ends against the post-ore Amikougami Creek fault (Map P.3558, back pocket). West of the fault, only a few isolated gold occurrences have been discovered so far. The sense and magnitude of the displacement along the Amikougami Creek fault are still poorly understood. Previous mapping (Thomson 1945) shows roughly 270 m apparent sinistral (west side south) offset of the Main Break along the fault. (As discussed earlier in this report, there are at least 2 and possibly 3 parallel fault structures east of the of the Amikougami Creek fault and it is not obvious which of the 2 or 3 was located west of it.) Underground exploration at the Macassa Mine revealed roughly 120 m of apparent sinistral displacement of the ‘04 Break, assuming that the east-northeast-striking structure encountered on the west side of the Amikougami Creek fault is the western continuation of the ‘04 Break. Exploration drifting on the 4750-foot level at Macassa traced this east-northeast-trending structure for up to 427 m, but no ore was found along the structure (Still 2001). As this structure is unmineralized, whereas mineralization along the ’04 Break extends vertically for 980 m from the 3825 to 7050-foot levels, the east-striking structure on the west side of the fault may not be the continuation of the ‘04 Break but is rather a parallel, unmineralized, fault (Still 2001). Determining the slip movement along the Amikougami Creek fault is therefore extremely important for discovering further 04 Break mineralization west of this fault.

The Amikougami Creek fault was examined underground on the 4750-foot level of the Macassa Mine. The fault strikes 340º and dips 70-75º east. It is a 1.3 m wide zone of chloritic gouge and breccia. Two thin (10 and 5-7 cm) diabase dikes are hosted by the fault. A syn-faulting foliation along the west margin of the fault zone is oriented clockwise to the fault walls, suggesting strike-slip sinistral (west side south) displacement. Fault-parallel striations plunge 10º north, which is consistent with subhorizontal strike-slip movement along the fault. At surface, the apparent displacement of mappable markers (e.g., from north to south: Timiskaming unconformity, syenite-porphyry intrusion, south tuff-conglomerate contact near the railroad turn, dikes of syenite porphyry, conglomerate-tuff contact southwest of Macassa shaft 3) is sinistral, but magnitude varies from about 90 to about 200 m, probably in part due to the uncertainty in positioning of most marker contacts. Data in Lackey (1990) show a roughly 200 m apparent sinistral displacement of a diabase dike located by drilling north of railroad turn at the Amikougami Creek crossing (the dike is not shown on Map P.3558), indicating a largely post-diabase timing of displacement.

Lackey (1990) analyzed marker displacement in the area north the Amikougami Creek railway crossing. He used specific stratigraphic units in the tuff package, a mafic syenite body, a diabase dike, and the ’04 Break as markers. The tuff unit shows apparent dextral displacement, whereas both the diabase dike and the ’04 Break show a left-lateral shift. The pattern was resolved through 800 m vertical (west side down) and 295 m horizontal sinistral movements. We agree with Still (2001) in that this large vertical offset is questionable. The big vertical component is largely a consequence of an assumed dextral displacement of tuff marker units. This dextral displacement disagrees with the opposite, sinistral shift of several other markers (see above), and, most importantly, of the tuff (north)-conglomerate (south) contact in the same area. The tuff-conglomerate contact is more distinct, and probably more reliable than lithologic markers within the tuff package. The discrepancy in apparent slip direction indicates that

marker horizons within the tuff package may have been correlated incorrectly across the fault. To date, there is no unequivocal evidence supporting large vertical movements on the Amikougami Creek fault. The available structural data support the latest strike-slip sinistral movement, however the possibility of earlier vertical movements should not be disregarded, and this critical fault displacement requires revision. Analysis of geological markers with different dip angles can help answering the question on whether only strike-slip movements or a combination of strike slip and vertical movements took place. However, at present, positioning of the potential markers in proximity to the fault is not sufficiently precise for such analysis. A review of existing drilling and ground magnetic data should be done to help in selecting reliable and precisely positioned markers. Among possible candidates are (from north to south): Timiskaming unconformity, tuff-conglomerate contact near the railroad Amikougami Creek crossing, 80-100 m wide syenite porphyry dike or sill immediately north of Macassa shaft #3, and a conglomerate-tuff contact southwest of Macassa shaft #3.

U-Pb and Re-Os Geochronology

Geochronological studies were done to determine the age of Kirkland Lake gold mineralization and assist in establishing relationships between hydrothermal activity, deformation, and magmatism. We attempted to date an ore-hosting syenite porphyry (feldspar-rich variety in classification of this report), two intramineral dikes and mineralized veins using the U-Pb and Re-Os methods. The U-Pb (Thermal Ionization Mass Spectroscopy, TIMS) and Re-Os analyses were done, respectively, at the Jack Satterly Geochronological Laboratory at the University of Toronto, and at the Radiogenic Isotope Facility at the University of Alberta. In-situ Sensitive High Resolution Ion Microprobe (SHRIMP) analysis of zircons was completed at the Geological Survey of Canada laboratory in Ottawa. Analytical techniques of U-Pb and Re-Os methods are discussed in Ayer et al. (2005), and Selby and Creaser (2004), respectively. The syenite porphyry sample (03JAA0006-geochronological sample, 004VOI1947-1-matching geochemical sample) was collected from the outcrop of the Main Break mineralization on the former Wright-Hargreaves property (Discovery outcrop, station 004VOI1947 of the present project). Samples of intramineral dikes are from stope 4529 (Macassa Mine, between the 4250 and 4500-foot levels) and surface outcrop 004VOI1518 (the large, foliated dike in Figure 39). Geochemical analyses of 3 samples are listed in Appendix A under sample names 004VOI1947-1 (syenite porphyry), 4529 (intramineral dike from stope 4529), and 004VOI1518-1 (intramineral dike from the surface outcrop). Three molybdenite-bearing samples are from active stopes of the Macassa Mine (stopes 4744, 4247-3, and 5030), and one (Tegren Gracie claim, the 5400-foot level, Macassa Mine) was contributed by the OGS Resident Geologist office in Kirkland Lake. Results of geochronological analyses are summarized below.

Evaluation of mineral concentrates from the 2 intramineral dike samples revealed an absence of mineral phases suitable for the U-Pb analysis. U-Pb dating of zircons from syenite porphyry returned complex results. TIMS ages of 5 single-grain fractions vary from 2700 to 2690 Ma (2700.2 ± 2.9 Ma, 2700.6 ± 4.4 Ma, 2694.4 ± 7.4 Ma, 2689.6 ± 4.7 Ma, 2689.7 ± 41.3 Ma; Figure 40). The youngest identifiable population is ca. 2690 Ma, which obviously indicates zircon inheritance, since Timiskaming clastic rocks that host syenite intrusions in the Kirkland Lake camp are younger than 2680 Ma (Corfu et al. 1991). The 12 in-situ SHRIMP dates form a near continuous range from about 2723 Ma to about 2675 Ma, accompanied by two outlying younger ages, 2649 Ma and 2642 Ma (Figure 41). One in-situ date (2673.5 ± 6.1 Ma) falls into a "geologically expected" range, but the textural setting of this spot age is uncertain. Overall, the data do not provide a reliable magmatic age. The two youngest in-situ SHRIMP ages likely reflect some metamorphic or hydrothermal zircon growth. Although the possibility of young magmatic ages cannot be completely discarded, it appears generally improbable: the youngest age comes from a diffuse overgrowth rim that does not show typical "magmatic" oscillatory zoning.

In summary, our U-Pb analyses have not produced definitive data on the age of the syenite porphyry and maximum age of Kirkland Lake mineralization, primarily due to the zircon inheritance problem. Although certainly disappointing, this result is not completely unexpected: constant presence of xenoliths is a diagnostic feature of Kirkland Lake syenite porphyries, and it can explain the abundance of inherited zircon. Future U-Pb studies may be able to overcome this problem by analyzing exceedingly larger number of zircon fractions and conducting more detailed in-situ (SHRIMP) analyses. Dating geologically older intrusive phases (mafic syenite and especially syenite) should also be considered.

Preliminary Re-Os results available at the time of report submission are summarized in Table 2. Of 4 model Re-Os ages, 3 are older than Timiskaming clastic rocks and cannot be geologically meaningful. Two of these ages are also not internally reproducible: aliquots of the same samples do not agree within 2σ errors. Two aliquots of sample 4744 produced internally consistent ages of 2666±12 Ma and 2677±11 Ma that comply with available broad geologic constraints. Separation of more molybdenite material from this sample is presently underway, and additional analysis in the near future may produce more certain results and allow better geologic assessment of Re-Os ages of this and other samples.

Although these Re-Os results are still preliminary, the complexity of the data is obvious, and this complexity most likely stems from chemical and crystallographic properties of molybdenite samples. All analyzed samples returned very low Re contents, which in other studies yielded poorly reproducible Re-Os dates (Selby and Creaser 2004). XRD analyses of samples 4744 and 5030 show that molybdenites belong to the 3R polytype. Virtually all existing Re-Os age dates are generated from the other, 2H polytype, that is far more typical for hydrothermal systems. Re-Os systematics of the 3R molybdenite have not been rigorously studied, and may potentially be very different from the better understood 2H systematics.

In summary, the results of U-Pb and Re-Os dating received to date do not provide independent constraints on the timing of gold mineralization. Zircon inheritance is clearly a major factor complicating the U-Pb dating. Additional Re-Os analysis of sample 4744 may bring a more precise result and help explain the meaning of other, anomalously old, ages.

Geochemistry of Kirkland Lake Gold-Bearing Veins

Geochemical data for auriferous quartz vein samples and brief characteristics of analyzed material are listed in Appendix A. Kirkland Lake gold veins are characterized by high Te, Mo, Pb, Ag (although for most samples with Au >50 g/t, Au/Ag ratios exceed 10), sporadically high Cu and normally low As. The most salient feature is the high tellurium content that exceeds gold values in all samples and shows well-defined positive correlation with gold (Figure 42). Previously published analyses of bulk ore samples from Lake Shore and Kirkland Lake Gold mines (Todd 1928; Thomson et al. 1950) show similar gold-tellurium relationships, confirming that the geochemical data presented here is representative of Kirkland Lake mineralization in general. Good gold-tellurium correlation indicates that presence of tellurides is the essential feature of Kirkland Lake gold mineralization, and that gold and tellurides most probably precipitated simultaneously through the same depositional mechanism.

Elevated Pb values in gold-bearing samples is largely due to the presence of altaite (PbTe). Altaite is the most abundant tellurium mineral in Kirkland Lake gold veins (Todd 1928; Thomson et al. 1950), and it also hosts practically all the lead, since galena is either absent or occurs in insignificant amounts, mainly as a post-ore mineral (Todd 1928; Thomson et al. 1950). Gold is present in native form or as tellurides: calaverite ($AuAgTe_2$) and rarer petzite (Ag_3AuTe_2) (Todd 1928; Thomson et al. 1950). Non gold-bearing tellurides, other than altaite, are rare (Todd 1928; Thomson et al. 1950). Assuming that all lead occurs in altaite, and the remaining tellurium is combined with gold and silver in calaverite, it is possible to estimate the proportions of native gold and telluride gold from chemical data (cf. Todd 1928, p.71). The ternary plot in Figure 43 demonstrates relative molecular proportions of combined gold and silver, tellurium and lead, and inferred modes of gold occurrence. Relatively high Pb/Te ratio of 4 samples (3 of which are low grade: Au ≤ 17 ppm) indicates that all tellurium occurs as altaite, and in 2 of these samples, the Pb/Te ratio significantly exceeds 1, implying the presence of galena. In all other samples, molecular proportions of tellurium exceed those of lead, indicating the presence of gold tellurides. Relative proportions of native and telluride gold vary significantly; 2 samples contain enough tellurium to bound all contained gold and silver in calaverite. There is no obvious relationship between gold grade and proportions of native vs. telluride gold, and no distinct spatial variations of Au-Pb-Te proportions, although the dataset is probably too small to reveal such trends. High molybdenum contents that are clearly related to the presence of molybdenite show no identifiable correlation to gold values.

Another interesting feature is the elevated vanadium content in sample 1254-2. This sample consists of cataclasized quartz cemented by dark-grey quartz-sericite matrix that hosts most gold and telluride grains. The presence of syenite porphyry clasts cannot explain the 350 ppm vanadium content (vanadium in this variety of syenite porphyry ranges from 50 to 75 ppm). Vanadium-bearing mica may be present in the mica-rich cement of the mineralized cataclasite. Previously, Kerrich and Watson (1984) reported V contents of up to 518 and 1716 ppm for the mafic syenite breccia ore at the Macassa Mine. These values significantly exceed vanadium contents in unaltered mafic syenites (e.g., 180-220 ppm, appendix A) and may also indicate the presence of vanadium-bearing mica in the ore. In this study, patches of bright green mica, macroscopically strongly resembling vanadium mica, roscoelite, were observed in altered syenite porphyries along the Mud Break. Microprobe analysis is needed to confirm the presence of vanadium mica in the hydrothermal assemblage of Kirkland Lake mineralization. Roscoelite is common for alkaline epithermal gold systems (e.g., Jensen and Barton 2000), and thus the presence of vanadium-rich mica in

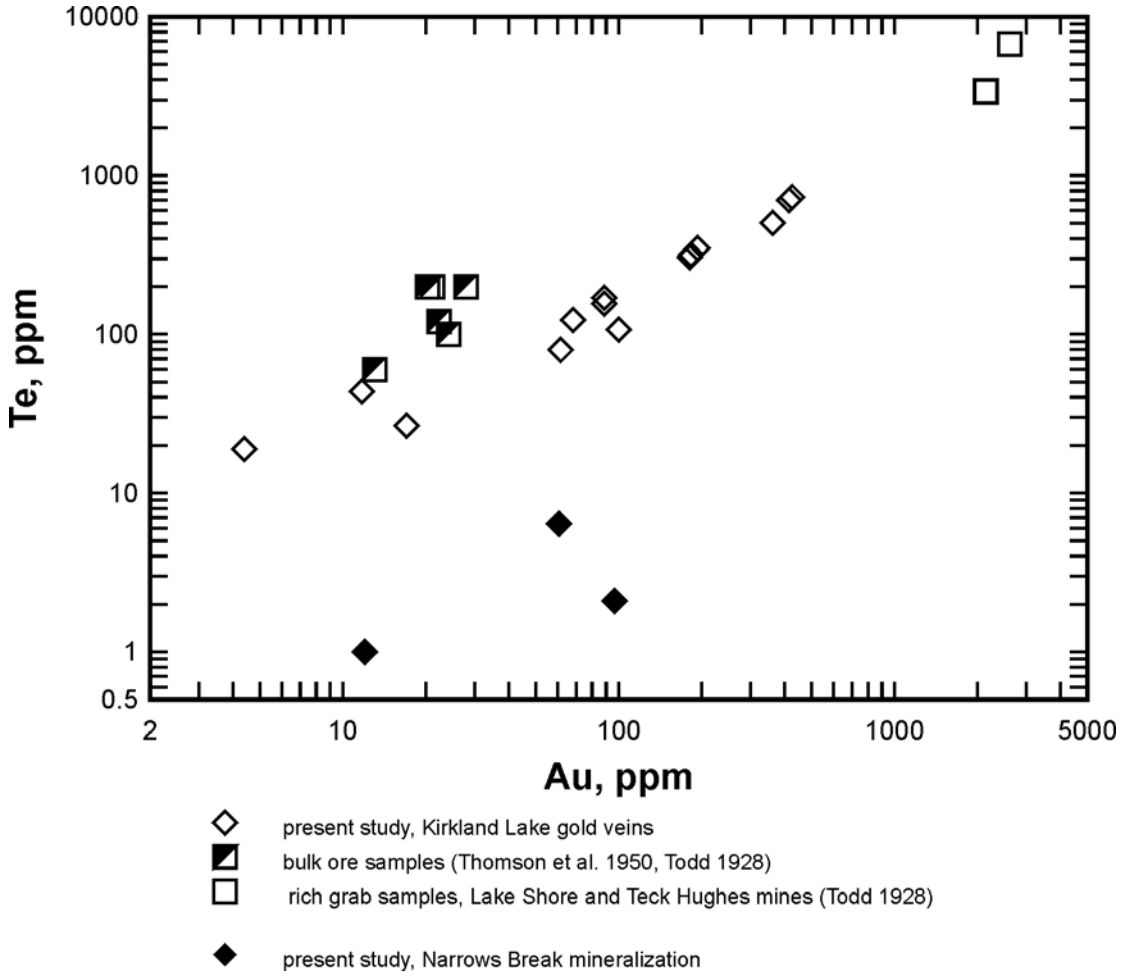

Figure 42. Au vs. Te plot for veins of the Kirkland Lake deposit and Narrows Break mineralized zone. Includes data for samples from this study (listed in Appendix A) and previously published data on bulk ore samples and gold-rich grab samples (Kirkland Lake Gold, Teck-Hughes and Lake Shore mines). Samples from Kirkland Lake gold veins of present study and grab samples of Todd (1928) show well-defined correlation of Au and Te and Au/Te<1. Bulk ore samples show similar relationships; a slight deviation from the trend is probably due to low resoulution of Te analyses in bulk samples (for most bulk samples Te is reported in %, to two decimals). Narrows Break mineralization is characterized by much lower Te values.

Kirkland Lake gold veins and alteration halos may provide important information on the genesis of mineralization.

The geochemistry of the Narrows Break mineralization differs from that of Kirkland Lake gold veins primarily by the lack of elevated Te (Figure 42), Mo, and Pb. This geochemical signature combined with already mentioned very different mineralization style (sheeted veinlets with abundant carbonate, stronger wall-rock carbonatization), suggests that the Narrows Break mineralized zone probably represents a separate mineralized system unrelated to Kirkland Lake mineralization.

Figures 44, 45, and 46 compare Kirkland Lake gold mineralization with other gold occurrences described earlier in this report. Kirkland Lake gold veins differ from all other mineralized zones by high Te (Te>Au), Mo, and low As. Te is also elevated in the Upper Canada L zone, however Te contents of

the L zone are lower than in Kirkland Lake ores, and no gold tellurides, only altaite, have been identified at Upper Canada. Other differences between the two deposits include higher As content and lower Au/Ag ratios of the Upper Canada mineralization. Apart from trace elements, another already mentioned important difference is the less intensive bulk wall-rock carbonatization at Kirkland Lake. The reason for this is not completely clear at present: available fluid inclusion data (although very fragmental) suggest presence of CO_2 – rich fluids in Kirkland Lake hydrothermal system (e.g., Watson 1984, p.184-188), and carbonic inclusions in mineralized quartz were also observed in this study.

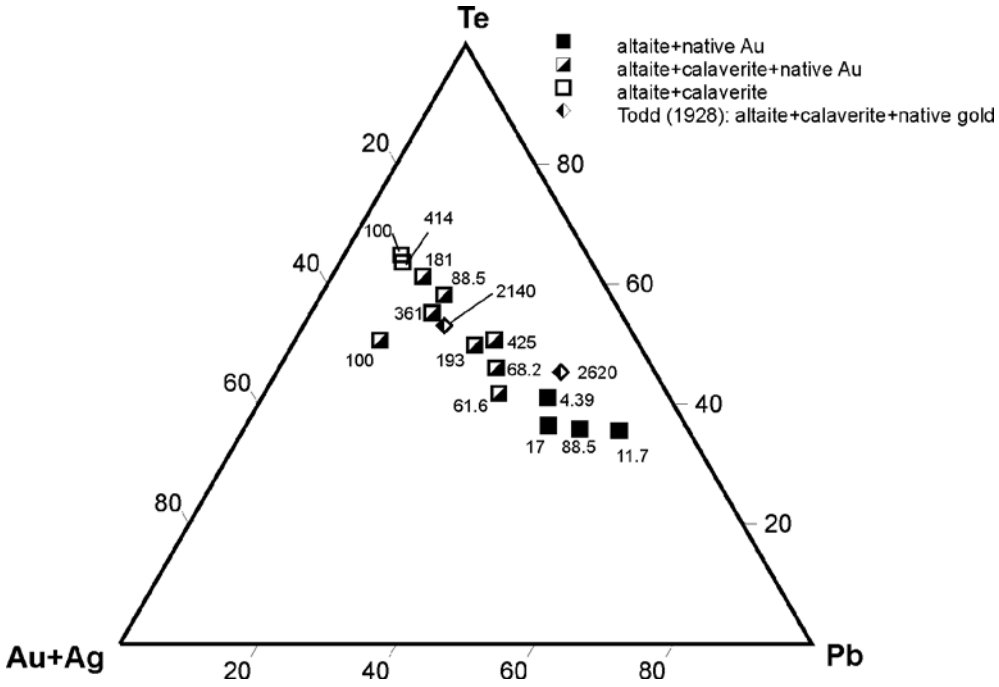

Figure 43. Ternary plot of molecular proportions of combined Au and Ag, Te, and Pb and probable mode of occurrence of gold. Te is assumed to combine with all contained Pb to form altaite (PbTe, the most abundant telluride in Kirkland Lake ores). The remaining Te is expected to form calaverite ($AuAgTe_2$), and the "excess" Au-Ag is assumed to be present in native form. Square and diamond symbols depict data of this study, and of Todd (1928), respectively. Filled symbols show samples in which amounts of Te are sufficient only to form altaite (or even insufficient to match all contained Pb), and thus all Au is likely to be present in native form. Half-filled symbols correspond to samples in which relative element proportions "allow" formation of altaite, calaverite, and presence of native Au. Open squares depict samples in which amounts of Te are sufficiently high to bind all contained Pb in altaite and all Au-Ag in calaverite (i.e., no native gold is present under above listed assumptions). Numbers depict Au (g/t). The apparent trend from the Pb apex to the Au+Ag-Te line corresponds to a general increase in the "telluride Au/native Au" ratio. The plot indicates that in virtually all (except 1) samples with Au > 50 g/t, Au tellurides are likely to be present, relative proportion of native and telluride Au ranges broadly and does not appear to be related to the gold grade.

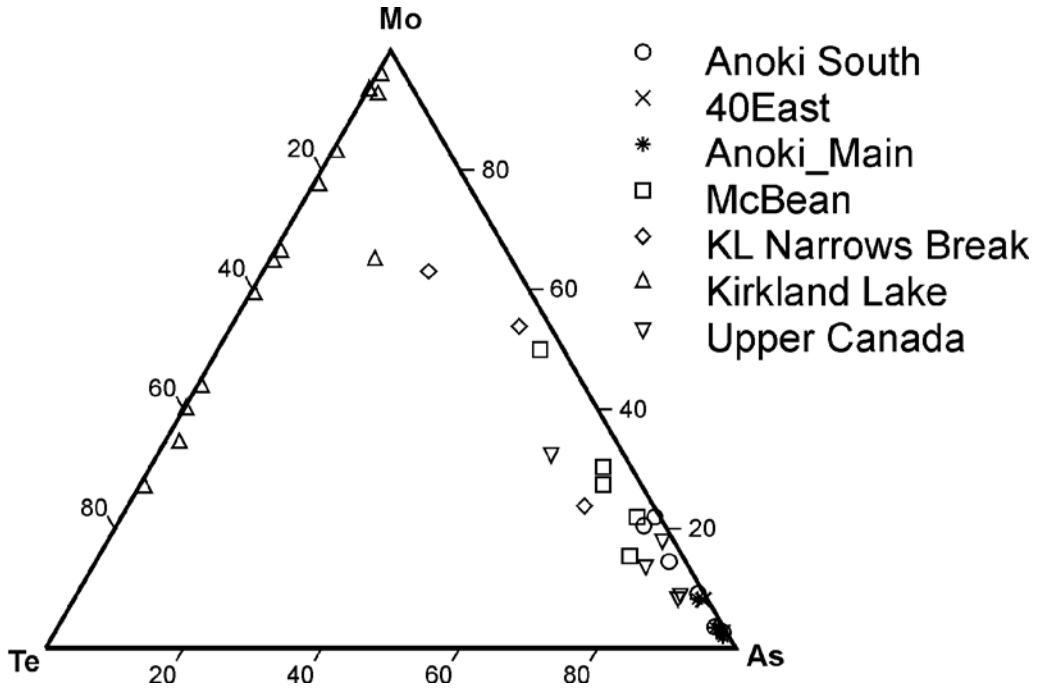

Figure 46. Te-Mo-As ternary plot (wt%) for samples of Kirkland Lake gold veins, Narrows Break mineralization, and mineralized zones of Gauthier Township transect.

Origin of Kirkland Lake Gold Mineralization

The origin of gold mineralization in the Kirkland Lake deposit was discussed in several publications, including Watson (1984), Kerrich and Watson (1984), Cameron and Hattori (1987), Robert and Poulsen (1997), and most recently in the Society of Economic Geologists Thayer Lindsley Lecture by Robert (2004). Watson (1984) and Kerrich and Watson (1984) proposed that Kirkland Lake mineralization was formed from 350-460ºC fluids of crustal, probably metamorphic, origin, with a possible contribution of magmatic fluids. This was followed by downward penetration of oxidizing, sulphate-bearing, and relatively low-temperature (<200ºC waning to approximately 50ºC) marine or meteoric fluids (Kerrich and Watson 1984). Cameron and Hattori (1987) documented evidence for oxidized fluids, such as the constant ^{34}S depletion of sulphides, presence of sulphates in veins and hematite in alteration halos, and proposed magmatic (oxidized felsic magma) fluid source. They also interpreted the syenitic intrusions as "slightly older" than mineralization and suggested that fluids were likely derived from magma at depth. Robert and Poulsen (1997) indicated that the Kirkland Lake vein array was formed in a late reverse-fault system overprinting folded Timiskaming rocks, i.e., it was emplaced in a setting similar to that of the Dome and Pamour deposits in Timmins. Robert (2001) introduced a new syenite-associated disseminated gold deposit group. These deposits tend to cluster along major faults and comprise variably developed quartz stockworks in intensely altered (albite and K-feldspar) wall rocks. The deposits are intimately associated with Timiskaming-age monzonitic to syenitic porphyry intrusions near the base of erosional remnants of Timiskaming-type sedimentary rocks. Mineralization was emplaced between 2682 Ma and 2672 Ma (i.e., broadly contemporaneous with Timiskaming sedimentation) and overprinted by regional fabric-forming deformation (Robert 2001). More recently, Robert (2004) classified the Kirkland Lake deposit as belonging to this group. In his interpretation, Robert (2004) proposed that the mineralization

was formed from fluids derived from the syenitic intrusive complex, it pre-dated D2, and was overprinted by subsequent deformation.

In agreement with the interpretations of Cameron and Hattori (1987) and Robert (2004), a very distinctive metal assemblage of Kirkland Lake veins strongly suggests that Kirkland Lake gold mineralization is genetically unrelated to other gold occurrences described in this report. As discussed below, Kirkland Lake high-grade gold veins were probably formed from compositionally distinct fluids derived from a different source than the fluids that deposited gold along the Larder Lake–Cadillac deformation zone and its splays. It is difficult to envision a mechanism that could generate the telluride- and molybdenite-rich mineralization that we see in Kirkland Lake veins from the same fluid that produced the typical low Te-Mo mineralization of the Larder Lake–Cadillac gold occurrences. Strong correlation of gold and tellurium suggests that both were deposited synchronously, and there was no superposition of discrete gold- and tellurium-rich mineralizing pulses. Synchronous introduction of gold and tellurium is also supported by the close mineralogical association of native gold and tellurides. The possibility that the distinct metal inventory of Kirkland Lake veins is not fluid source-related but instead reflects host rock signature inherited through fluid-rock interactions at the final stages of fluid migration, cannot be completely discarded but appears improbable. There is no evidence for volumetrically significant fluid-wall rock exchange, as the alteration halos directly associated with Kirkland Lake veins are relatively small. Besides, mineralization is hosted by geochemically variable rocks (e.g., mafic syenite, syenite porphyry, tuff, conglomerate), however no chemical or mineralogical zoning reflecting the host lithologies has been noticed to date. Thus, most probably, geochemistry of Kirkland Lake mineralization reflects the fluid chemistry, which was originally different from that of gold-bearing fluids that migrated and deposited gold in the Larder Lake–Cadillac deformation zone and its immediate splays. Consequently, the Kirkland Lake gold deposit is unlikely to be part of the regional hydrothermal system associated with the Larder Lake–Cadillac deformation zone.

Amongst all potential fluid sources, derivation of the fluids from alkaline magmas appears most likely. The Kirkland Lake gold deposit shares strong analogies with epithermal-style gold deposits associated with alkaline magmatism (Jensen and Barton 2000). The best known Phanerozoic deposits of this group are Emperor (Fiji) and Cripple Creek (Colorado, USA; Jensen and Barton 2000). Several key geological parameters of the Kirkland Lake deposit are typical for epithermal-style systems related to alkaline magmatism. These include high-grade (low base-metal) veins, high Au/Ag ratios, high tellurium contents (e.g., Te>Au at Kirkland Lake), presence of gold tellurides, common presence of molybdenite, K-metasomatism (e.g., sericitization at Kirkland Lake), and spatial association of mineralization with the multi-phase alkaline igneous complex. In addition, there are less pronounced or less well established features of the Kirkland Lake mineralization that are also common to alkaline-related epithermal systems, such as the occurrence of vanadium mica, and presence of sulphates, hematite, and possibly magnetite (e.g., Cameron and Hattori 1987; Watson and Kerrich 1984). Strong structural control of gold-bearing veins is also common for epithermal-style deposits related to alkaline magmatism (Jensen and Barton 2000).

The main weakness of the magmatic fluid model is the absence of causative plutons. Presently available data are insufficient to link mineralization to any specific intrusive phase. The U-Pb and Re-Os analyses of this project have not produced reliable geochronological constraints on the relative timing of magmatism and mineralization. Structural relationships indicate that mineralization post-dated the emplacement and crystallization of the syenite porphyry (i.e., the latest phase of the composite alkalic stock), since the gold-bearing Main Break crosscuts and displaces the syenite porphyry intrusion. Hicks and Hattori (1988) reported that gold-related alteration overprints syngenetic syenite porphyry alteration, and thus genetic relationships between mineralization and syenite porphyries that are presently exposed at surface are unlikely. This, however, does not rule out the possibility of a magmatic origin for the gold-bearing fluids: the mineralizing fluids could have been derived from a distal magmatic source at depth as

suggested by Cameron and Hattori (1987). The occurrence of alkaline intramineral dikes confirmed by this study indicates that alkaline magmatism had not ended by the time of gold mineralization, an active magmatic chamber existed at depth and could have served as a fluid source.

Based on a) the relative chronology of gold-bearing quartz veins, intramineral dikes and deformational fabrics, b) the presence of S4-parallel syn-mineralization stylolites in gold-bearing veins, c) syn-mineralization cataclasis in gold veins indicative of syn-mineralization fault movements, and d) the compatibility of the inferred reverse-dextral movement on the Main Break with the northwest-southeast compression direction of D4, we propose that the mineralization could have formed relatively early in the D4 event. Syn-D4 timing of gold mineralization does not preclude the alkalic magmatic fluid source, because at present there is no evidence that would qualify the alkalic magmatism as entirely pre-deformational. For example, two large alkalic plutons in the area, the Lebel Stock and the Murdock Creek pluton, are interpreted as syn-D2 (Wilkinson et al. 1999); it is also possible that magmatism partly overlapped with D4.

The style and composition of the quartz-carbonate sheeted-veinlet mineralized zone of the Narrows Break differ from those of typical Kirkland Lake gold veins and is overall more similar to the gold occurrences along the Larder Lake–Cadillac deformation zone. Most probably, the Narrows Break represents a separate hydrothermal system. Documented structural relationships indicate that the Narrows Break mineralization was formed broadly synchronous with D4.

Summary

DEFORMATION HISTORY

We identify 3 post-Timiskaming fabric-forming deformation events, which occurred after an early syn- to post-Timiskaming deformation that did not generate deformational fabrics. This early (non fabric-forming) deformation is marked by bedding reversals in Timiskaming turbidites. The maximum age of turbidites (2677.7 ± 3.1 Ma) constrains the maximum age of this deformation event. The earliest fabric-forming event, D2, is related to oblique dextral reverse movements along the Larder Lake–Cadillac deformation zone (documented in Gauthier Township) and characterized by penetrative S2 foliation. This deformation is overall compatible with north-south shortening as previously suggested by Wilkinson et al. (1999), however, we do not find evidence for sinistral movements along northeast-trending segments of the Larder Lake–Cadillac deformation zone. D3 corresponds to an east-west shortening event that locally produced a north-trending S3 foliation. D4 is related to northwest-southeast shortening and manifested by a regional steep northeast-trending foliation. The occurrence of an east-west shortening event (D3) between D2 and D4 does not support previous interpretations of a prolonged progressive deformation from D2 to D4 (e.g., Toogood and Hodgson 1986).

GOLD MINERALIZATION

Hodgson and Hamilton (1989) linked the formation of gold deposits of the Kirkland Lake–Larder Lake area to the final stages of D4 (D2 under the original authors' nomenclature), and implied a single regional fluid source for gold mineralization. Our results suggest that gold mineralization is associated with D2 and D4, and it probably involved more than one fluid source.

Gold-bearing veins along the brittle to brittle-ductile Kirkland Lake fault (Main Break) were formed at relatively shallow crustal levels, probably simultaneously with reverse-dextral to reverse movement on the Main Break. Mineralization was likely emplaced early during D4. The distinct metal inventory (Te>Au, Mo, Pb, Ag, high Au/Ag, low As) of Kirkland Lake mineralization indicates a separate fluid source, different from gold deposits and occurrences clustering along the Larder Lake–Cadillac deformation zone and its splays. Based on presently available data, a deep alkaline magmatic fluid source (magmatic chamber or intrusion at depth) appears most probable. The interpretation of Kirkland Lake as a stand-alone hydrothermal system probably related to alkalic magmatism and unrelated to gold mineralization along the Larder Lake–Cadillac deformation zone agrees with the interpretation of Robert (2004). However, the syn-D4 timing of mineralization proposed in this report differs from the pre-D2 timing suggested by Robert (2004). The Narrows Break mineralized zone located about 350 m north of the Main Break differs in style, geochemistry, and alteration from typical Kirkland Lake gold veins and most likely represents a separate hydrothermal system. Relationships between S4 and sheeted veinlets of the Narrows Break mineralized zone indicate that they were formed during D4.

Gold mineralization in Gauthier Township represents a separate and older hydrothermal event than that of the Kirkland Lake gold lodes. Mineralization at the Upper Canada Mine occurs in a high-strain ductile deformation zone that probably represents a splay of the Larder Lake–Cadillac deformation zone. Although hydrothermal activity spanned 3 deformation phases (D2, D3, and D4), gold was introduced relatively early, during D2, and was accompanied by strong bulk carbonatization. Subsequent deformation and, possibly, hydrothermal activity overprinted gold mineralization. The effect of this overprint on key geological and economical parameters of gold mineralization is unclear.

Gold occurrences of the Anoki and McBean properties are localized within or in the immediate proximity of the first-order Larder Lake–Cadillac deformation zone. Gold occurs in sulphidized Fe-tholeiite flows (Anoki Main zone), in quartz stockworks within carbonate- and carbonate-fuchsite-altered ultramafic rocks (“green carbonate”, McBean and Anoki Deep zones), in quartz-sulphide zones hosted by Timiskaming clastic rocks and locally associated with feldspar-phyric dikes (40 East zone), and in quartz veining with sulphides in cherty to graphitic exhalite horizons enclosed in basalts (Anoki South). In all cases mineralization is accompanied by strong carbonatization. Drill cores from the McBean zone show that mineralization and alteration are most likely synchronous with the development of D2 fabrics. Mineralized zones at the Anoki and McBean properties are part of a regionally extensive hydrothermal system that affected a roughly 20 km long segment of the Larder Lake–Cadillac deformation zone from the Kerr Addison-Chesterville gold deposit (east) to the Anoki occurrences (west). Other similar gold deposits include the Cheminis and Omega deposits in McVittie Township. Most gold production and reserves are from sulphide-rich replacement ores in mafic (mostly tholeiitic) volcanic rocks, whereas native-gold-bearing quartz stockworks in carbonate-fuchsite-altered meta-ultramafic rocks (“green carbonate ore”) are second in importance. Gold deposits and occurrences along the Larder Lake–Cadillac and Upper Canada deformation zones are probably related because they have similar geochemical signatures and similar ore zone plunges roughly parallel to L2. The Upper Canada deformation zone is a splay of the Larder Lake–Cadillac deformation zone, and as both structures are syn-D2, they were likely hydraulically connected during the introduction of gold-bearing fluids along these structures.

Acknowledgements

We thank Queenston Mining Inc. and Kirkland Lake Gold Inc. for granting access to their properties, surface and underground workings, and drill core, and for contributing private geological data that were extensively used in this project. Kirkland Lake Gold Inc. provided logistical support for underground work of the first author. Geologists Dale Alexander, Frank Ploeger of Queenston Mining Inc., Mike Sutton, Stewart Carmichael, Ken Rattee, Duncan Quick and Cory Dupuis of Kirkland Lake Gold Inc., and

Chris Pegg (consultant) are thanked for their time and sharing their knowledge of geology and gold mineralization of the Kirkland Lake camp and Kirkland Lake–Larder Lake gold area. We aslo thank Erle Boyce, Eric Marion, and Michael Leahy for allowing access to outcrops on their properties. Strong interest in the project from geologists and prospectors of the Kirkland Lake–Larder Lake area is gratefully acknowledged. The first author was capably assisted in the field by Jennifer Cardamone and Patrick Johnson in 2003, and Natasha Lallier in 2004. Ms. Lallier also actively participated in preparing digital data for geological map P.3558. The project was supported by the Discover Abitibi Initiative, a regional cluster economic development project based on geoscientific investigations of the western Abitibi greenstone belt. The initiative is centred on the Kirkland Lake and Timmins mining camps and directed by local stakeholders. FedNor, Northern Ontario Heritage Fund Corporation and private sector investors provided the funding for the initiative.

Appendix A

Geochemical Data

This appendix consists of 6 tables: tables A.1 and A.2 contain lithogeochemical data intended for protolith characterization (major elements, REE, HFSE, etc.); tables A.3, A.4, and A.5 contain pathfinder trace element and major element (A.5) data for mineralized samples. Table A.6 contains brief descriptions of mineralized samples. Data for Upper Canada Mine samples are listed in tables A.1 and A.4 (with some overlap). Negative values correspond to values below detection limits.

Abbreviations:

Geolabs – Geoscience Laboratories, Ontario Ministry of Northern Development and Mines
Actlabs – Activation Laboratories Ltd (Ancaster, Ontario)
XRF – X-ray fluorescence
IRC – infra-red absorption
ICP-MS – closed beaker solution, inductively coupled plasma mass-spectrometry
H. ICP-MS – proprietary digestion, ICP-MS analysis
ICP-AES – closed beaker solution, inductively coupled plasma atomic emission spectroscopy
MS-AHT – hydride, inductively coupled plasma mass-spectrometry
MS-IAT – fire assay with ICP-MS finish
ICP-OES – four acid solution, inductively coupled plasma optical emission spectrometry
INAA – instrumental neutron activation analysis
Fire, grav. – fire assay with gravimetric finish
AAS-Flame – beaker solution, atomic absorption spectroscopy

Unit codes:

Alkalic Intrusives	13
Alkalic Volcanics	5
Felsic to Intermediate Intrusive	12
Mafic Intrusive	10
Mafic Volcanic	2
Temiskaming Sediments	8
Ultramafic Volcanic	1

Deposit/ mineralized zone	Township	Sample ID	Sample type	Station/drill hole/stope	Depth from (ft)	Depth to (ft)	utm_nad83_E	utm_nad83_N	Description of material sampled
KL Narrows Break	Teck	004VOI1520-1	surface	004VOI1520			569871	5333226	carbonate-quartz veinlets in coarse sandstone
KL Narrows Break	Teck	004VOI1522-1	surface	004VOI1522			569877	5333231	carbonate-quartz veinlets in coarse sandstone
KL Narrows Break	Teck	004VOI1523-1	surface	004VOI1523			569882	5333238	carbonate-quartz veinlets in augite syenite
Kirkland Lake (Macassa)	Teck	3829	underground	stope 3829					quartz vein associated with '04 Break (full vein width, approx. 10-15 cm)
Kirkland Lake (Macassa)	Teck	3829-2	underground	stope 3829					'04 Break mineralization; veinlet (0.5-1 cm thick) swarm, in silicified and pyritized augite syenite
Kirkland Lake (Macassa)	Teck	3829D	underground	stope 3829					'04 Break mineralization; vein fragment; dark quartz, molybdenite slips
Kirkland Lake (Macassa)	Teck	4206	underground	stope 4206					Moderately (approx. 30°) south-dipping hanging wall vein; full vein width (approx. 30 cm); white, grey and dark grey quartz (4206-S3 vein)
Kirkland Lake (Macassa)	Teck	4229-5Q	underground	stope 4229-5					South dipping (approx. 55-60°) vein in proximal hanging wall of the '04 Break; full vein width (approx. 10 cm; stope 4229, sublevel 5)
Kirkland Lake (Macassa)	Teck	4506	underground	stope 4506					Shallowly (0-20°) south-dipping hanging wall vein; full vein width (approx. 15 cm), quartz and fragments of mafic syenite (approx. 2/3 proportion)
Kirkland Lake (Macassa)	Teck	4528	underground	stope 4528					North-dipping (approx. 60°) vein, hanging wall of the '04 Break; full vein width (approx. 30 cm)
Kirkland Lake (Macassa)	Teck	4744	underground	stope 4744					Shallowly (approx. 20-25°) south dipping hanging wall vein; full vein width (approx. 15 cm), minor mafic syenite material
Kirkland Lake (Macassa)	Teck	4940-1	underground	stope 4940					'04 Break mineralization; full vein width (25-30 cm), largely white quartz, some dark quartz in the axial part
Kirkland Lake (Macassa)	Teck	4940-3	underground	stope 4940					'04 Break mineralization; irregular vein of dark quartz with diffuse contacts; vein fragment: dark fine-grained quartz
Kirkland Lake (Macassa)	Teck	4512-2	underground	stope 4512					South dipping (approx. 45°) hanging wall vein; full vein width (approx. 5-7 cm); mainly white quartz, minor host rock (tuff) material
Kirkland Lake (Teck Hughes)	Teck	1254-1	surface	004VOI1254			570493	5333201	vein fragment, Teck Hughes #1 vein, typical breccia vein: angular porphyry clasts (up to 20%) cemented by white quartz
Kirkland Lake (Teck Hughes)	Teck	1254-2	surface	004VOI1254			570493	5333201	vein fragment; Teck Hughes #1 vein, dark cataclasized quartz

INTRUSIVE CONTACT

ARCHEAN

13 Alkalic Intrusive Rocks

Feldspar-phyric to aphyric trachyte; syenite porphyry, diorite, lamprophyre

Amphibole-phyric trachyandesite

INTRUSIVE CONTACT

12 Felsic to Intermediate Intrusive Rocks: feldspar porphyry, quartz-feldspar porphyry, aplite

INTRUSIVE CONTACT

10 Mafic Intrusive Rocks: amphibolitized gabbro

INTRUSIVE CONTACT

8 Timiskaming-Type Clastic Metasedimentary Rocks

Volcaniclastic sandstone and polymictic conglomerate associated with volcanic rocks

Conglomerate with some interbedded sandstone

Turbidistic sandstone-siltstone assemblage; subordinate argillite

Sandstone (commonly chloritic); subordinate siltstone, argillite and chlorite schist; locally some interbedded conglomerate

7 Chemical Metasedimentary Rocks: exhalite, chert

5 Alkalic Metavolcanic Rocks

Aphyric to porphyritic flows, volcanic breccia, volcaniclastic breccia

Tuff, tuff breccia

4 Felsic Metavolcanic Rocks: tuff, volcanic breccia

2 Mafic Metavolcanic Rocks: basalt

1 Ultramafic to Mafic Metavolcanic Rocks[c]: chlorite schist, talc-chlorite schist, carbonate-fuchsite schist

[a] This is a field legend and may be changed as a result of subsequent laboratory investigations.

[b] The rock unit codes for this legend were designed for use with a database of geoscience information related to the Discover Abitibi Initiative. As a result, not all codes used in the database are shown in this legend.

[c] The letters "G", "C" and "D" preceding a code refer, respectively, to data interpreted from published geophysical maps, compiled from the geological map of Gauthier Township by Thomson and Griffis (1941), and interpreted from diamond-drill-hole data.

[d] Rock codes "2" within polygons of unit 1 indicate more probable mafic prololith.

SYMBOLS

- Area of bedrock outcrop
- Small bedrock outcrop
- Lithologic contact; (observed, approximate)
- Lithologic contact; interpreted (sharp, gradational)
- Lithologic contact; interpreted from geophysics
- Denotes areas of extensive drift through which geologic contacts cannot be reliably extrapolated
- Fault; inferred
- Graded bedding; facing direction known (inclined, overturned)
- Cross-bedding; facing direction known (overturned)
- Bedding; unsubdivided, facing direction unknown (inclined, vertical)
- Foliation; second generation (inclined, vertical)
- Foliation; third generation (inclined)
- Foliation; fourth generation (inclined, vertical)
- Stretching and mineral lineation
- Area of high strain corresponding to major deformation zone
- Occurrence, keyed to list
- Selected gold-bearing mineralized zone
- Open pit
- Shaft, shaft site
- Diamond drill-hole location[a]
- Road, trail
- Railway line
- Pipeline, power line

Horizontal projection of selected diamond drill-hole, showing lithologies and depth (in metres) to specific lithologic contact. To accommodate the scale, lithologic intervals are generalized, small dikes and sills are not shown.

[a] Some diamond drill-holes are slightly displaced from their actual location, to enhance legibility. Not all diamond drill-holes are shown.

OCCURRENCE SIZE

- Past Producing Mine
- Prospect
- Occurence

EXPLANATION OF ROCK CODES

This map uses codes that are to be read from left to right.

① ③
4CTfgAT
② ④

① The lithology code (4) identifies the main lithologic unit within a polygon or outcrop. Lithology codes correspond to units listed in LEGEND, at left. The letters "C", "G" or "D" preceding a lithology code refer to, respectively, information compiled from previously published sources, information interpreted from geophysical data, and information derived from drill-hole logs.

② The primary rock type code (CT) identifies subdivisions of the main lithologic unit. Explanations of rock type codes are listed below under "Rock Type".

③ The texture code (fg) supplies additional information about the texture of the rock. Explanations of texture codes are listed below under "Textural Description".

④ The secondary rock type code (AT), where present, identifies a second, less abundant rock type within the polygon or outcrop. These codes are the same as those listed under "Rock Type".

Using the legend and the explanations listed below, therefore, 4CTfgAT indicates a polygon or outcrop of felsic metavolcanic rock, composed primarily of fine-grained cherty tuff, with subordinate ash tuff.

4CTfgAT

Rock Type		Textural Description

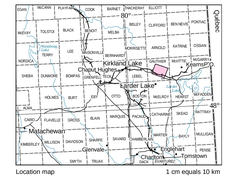
This map is published with the permission of the Director, Ontario Geological Survey.



1 cm equals 10 km

This geologic map represents one of the products of the Greenstone Architecture Project of the Discover Abitibi Initiative, which was designed to stimulate mineral exploration in the Ontario portion of the Abitibi greenstone belt and has components that range from geophysical surveying to deposit-scale mapping (see Ayer et al. 2003). This map presents results from the first year of the Gold Subproject 2 study, as summarized in Isposlatov, Lafrance and Dubé 2003.

Cette carte géologique représente un des produits découlant du projet relatif à la ceinture de roches vertes architecturale, lequel s'inscrit dans le cadre de l'initiative *Découvrons l'Abitibi*, conçue pour stimuler l'exploration minérale dans la section ontarienne de la ceinture de roches vertes de l'Abitibi et constituée de diverses composantes, depuis les levés géophysiques jusqu'aux cartes à l'échelle du gisement (voir Ayer et al. 2003). Cette carte présente les résultats de la première année de l'étude portant sur le sous-projet 2 relatif à l'or, résumée dans Isposlatov, Lafrance et Dubé 2003.

Ayer, J.A., Thurston, P.C., Dubé, B., Fowler, A.D., Gibson, H.L., Hudak, G., Lafrance, B., Lesher, C.M., Piercey, S.J., Reed, L.E. and Thompson, P.H. 2003. Overview of the Discover Abitibi Greenstone Architecture project: subprojects, goals and results; in Summary of Field Work and Other Activities 2003, Ontario Geological Survey, Open File Report 6120, p.32-1 to 32-12.

Isposlatov, V., Lafrance, B. and Dubé, B. 2003. Discover Abitibi. Gold Subproject 2. Geologic mapping of the Gauthier Township transect (Kirkland Lake gold camp); in Summary of Field Work and Other Activities 2003, Ontario Geological Survey, Open File Report 6120, p.35-1 to 35-5.

SOURCES OF INFORMATION

Base map information data derived from the Ontario Land Information Warehouse, Land Information Ontario, Ontario Ministry of Natural Resources, scale 1:20 000. Universal Transverse Mercator (UTM) co-ordinates are in North American Datum 1983 (NAD 83), Zone 17.

Compiled geology derived from:
Thomson, J.E. and Griffis, A.T. 1941. Geology of Gauthier Township, East Kirkland Lake area; Ontario Department of Mines, Annual Report, 1941, v.50, pt.8, 29p. Accompanied by Map 50c, scale 1 inch to 1000 feet.

Geophysical data derived from:
Ontario Geological Survey 2002. Ontario airborne geophysical surveys, magnetic and electromagnetic data, Kirkland Lake area; Ontario Geological Survey, Geophysical Data Set 1102rev.

Compiled drill-hole data derived from the assessment files, Resident Geologist's office, Kirkland Lake, and from unreleased drill logs provided by Queenston Mining Inc.

Locations of Anoki Deep zone, Anoki South zone, 40 East zone, 80 East zone and Murphy shaft zone derived from press releases and project information files by Queenston Mining Inc., posted at www.queenston.ca, accessed fall/winter 2003.

Locations of Upper Canada "H" and "M" zones are compiled from Thomson and Griffis (1941).

Metric conversion factor: 1 foot = 0.3048 m (0.304 m for drill-hole data).

Magnetic declination approximately 12°W at the centre of the map area in 2003.

EXPLANATION OF ROCK CODES

This map uses codes that are to be read from left to right.

1 3

8SStgCG

2 4

① The lithology code (8) identifies the main lithologic unit within a polygon or outcrop. Lithology codes correspond to units listed in LEGEND, at left. The letters "C", "D" or "D" preceding a lithology code refer to, respectively, information compiled from previously published sources, information interpreted from geophysical data, and information derived from drill-hole logs.

② The primary rock type code (SS) identifies subdivisions of the main lithologic unit. Explanations of rock type codes are listed below under "Rock Type".

③ The texture code (tg) supplies additional information about the texture of the rock. Explanations of texture codes are listed below under "Textural Description".

④ The secondary codes (CG), where present, identify a second, less abundant lithologic unit and rock type within the polygon or outcrop. These codes are the same as those listed under LEGEND, "Rock Type" and, where applicable, "Textural Description".

Using the legend and the explanations listed below, therefore, 8SStgCG indicates a polygon or outcrop of Timiskaming-type metasedimentary rocks composed primarily of fine-grained sandstone, with subordinate conglomerate.

8SStgCG

Rock Type		Textural Description	
AG	Argillite	am	amygdaloidal

- Thomson, 1945
- Todd, 1928
- Unpublished company maps provided by Kirkland Lake Gold Inc.

SOURCES OF INFORMATION

Base map information derived from the Ontario Land Information Warehouse, Land Information Ontario, Ontario Ministry of Natural Resources, scale 1:20 000. Universal Transverse Mercator (UTM) co-ordinates are in North American Datum 1983 (NAD 83), Zone 17.

Compiled geology derived from:
MacLean, A. 1944. Township of Lebel, District of Timiskaming, Ontario; Ontario Department of Mines, Map 53a, scale 1:12 000.

Thomson, J.E. 1945. Township of Teck, District of Timiskaming, Ontario; Ontario Department of Mines, Map 1945-1, scale 1:12 000.

Todd, E.W. 1928. West sheet, Central ore zone and vicinity, Kirkland Lake gold area, Ontario Department of Mines, Map 37a-1, scale 1:2400.

———1928. Central sheet, Central ore zone and vicinity, Kirkland Lake gold area, Ontario Department of Mines, Map 37a-2, scale 1:2400.

Unpublished company maps provided by Kirkland Lake Gold Inc.

Geophysical data derived from:
Ontario Geological Survey 2004. Ontario airborne geophysical surveys, magnetic data, grid data (ASCII format) and vector data, Kirkland Lake – Larder Lake area; Ontario Geological Survey, Geophysical Data Set 1053a.

Ontario Geological Survey 2004. Ontario airborne geophysical surveys, magnetic data, grid data (Geosoft® format) and vector data, Kirkland Lake – Larder Lake area; Ontario Geological Survey, Geophysical Data Set 1053b.

Metric conversion factor: 1 foot = 0.3048 m (0.304 m for drill-hole data).

Magnetic declination approximately 12°W in 2004.

CREDITS

Geology by V.O. Ispolatov, 2004.

Digitization and preparation of GIS product by V.O. Ispolatov and N. Lallier.

Cartographic production by A. Evers.

Geologic mapping and research supported by the Discover Abitibi Initiative under contract awarded to the Mineral Exploration Research Centre (MERC), Laurentian University, Sudbury, Ontario.

Contract management, project management by Robert Calhoun, Project Manager, Discover Abitibi Initiative.

Overall project management by Timmins Economic Development Corporation.

Laurie Reed (consulting geophysicist) integrated data and generated custom plots of total magnetic field and first vertical derivatives of total magnetic field for Discover Abitibi.

Discover Abitibi Initiative
The Discover Abitibi Initiative is a regional, cluster economic development project based on geoscientific investigations of the western Abitibi greenstone belt. The initiative, centred on the Kirkland Lake and Timmins mining camps, will generate 19 projects developed and directed by the local stakeholders. FedNor, Northern Ontario Heritage Fund Corporation, municipalities and private sector investors have provided the funding for the initiative.

Initiative Découvrons l'Abitibi
L'initiative *Découvrons l'Abitibi* est un projet de développement économique régional dans une grappe d'industries, projet fondé sur des études géoscientifiques de la ceinture de roches vertes de l'Abitibi occidental. Cette initiative, centrée sur les zones minières de Kirkland Lake et de Timmins, mènera à bien 19 projets élaborés et dirigés par des intervenants locaux. FedNor, la Société de gestion du Fonds du patrimoine du Nord de l'Ontario, municipalités et des investisseurs du secteur privé ont fourni les fonds de cette initiative.

This geologic map represents one of the products of the Greenstone Architecture Project of the Discover Abitibi Initiative, which was designed to stimulate mineral exploration in the Ontario portion of the Abitibi greenstone belt and has components that range from geophysical surveying to deposit-scale mapping (see Ayer et al. 2003). This map presents results from the second year of the Gold Subproject 2 study, as summarized in Ispolatov, Lafrance and Dubé 2004.

Cette carte géologique représente un des produits découlant du projet Architecture de la ceinture de roches vertes de l'Initiative Découvrons l'Abitibi dans le cadre de l'initiative découvrons l'Abitibi, laquelle pour stimuler l'exploration minérale dans la section ontarienne de la ceinture de roches vertes de l'Abitibi et constitue de diverses composantes, depuis les levés géophysiques jusqu'aux cartes à l'échelle du gisement (voir Ayer et al. 2003). Cette carte présente les résultats de la deuxième année de l'étude portant sur le sous-projet 2 relatif à l'or, résumée dans Ispolatov, Lafrance et Dubé 2004.

Ayer, J.A., Thurston, P.C., Dubé, B., Fowler, A.D., Gibson, H.L., Hudak, G., Lafrance, B., Lesher, C.M., Piercey, S.J., Reed, L.E. and Thompson, P.H. 2003. Overview of the Discover Abitibi Greenstone Architecture project: subprojects, goals and results; in Summary of Field Work and Other Activities 2003, Ontario Geological Survey, Open File Report 6120, p.32-1 to 32-12.

Ispolatov, V., Lafrance, B. and Dubé, B. 2004. Discover Abitibi. Gold Subproject 2: Geologic mapping and gold mineralization studies, Kirkland Lake gold camp (Gauthier and Teck townships); in Summary of Field Work and Other Activities 2004, Ontario Geological Survey, Open File Report 6145, p.42-1 to 42-6.
